#### SYPHILIS AND TABES DORSUALIS.\*

By B. SACHS, M.D.,

PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST TO MOUNT SINAH HOSPITAL; PRESIDENT OF THE AMERICAN NEUROLOGICAL ASSOCIATION, ETC.

Or the causal relation between syphilis and tabes there can no longer be any doubt. The question has been definitely settled by Erb's † recent statistics proving previous syphilitic infection in at least eighty-nine per cent. of tabic patients and in only twenty-two and a half per cent. of hospital patients suffering from other diseases. This latter percentage is based upon an analysis of 5,500 cases. The importance of syphilis as an ætiological factor of tabes has received additional support, to my mind, from the utter failure of Leyden ‡ to break down the value of Erb's statistics.

But aside from mere statistical evidence, which is never entirely unobjectionable, the close relation between syphilis and tabes is brought to light in other ways. I will mention a few facts briefly in the order in which they have impressed themselves upon me:

- The frequent development of general paresis after tabes and of tabic symptoms in the course of general paresis, the latter also being much more apt to occur in syphilitic subjects than in others.
- Cases of tabes, and for that matter of general paresis as well, occurring in women and in very young subjects are invariably preceded by syphilis, which may be acquired or hereditary.
- In cases of undoubted cerebral syphilis or of cerebro-spinal syphilis, symptoms occur which, on the one hand, may resemble general paresis, and on the other tabes.

My attention has been directed particularly to this last point during the past three years, and I have given details in previous articles.\* I have in mind at this writing a

covery from cerebral syphilis, the knee-jerks returned and the pupils began to contract, though sluggishly, to light. In one case, however, in which the mental symptoms of syphilis and a syphilitic hemiplegia at the age of thirty-five were entirely recovered from more than a year since, and the pupils react normally, the knee-jerks are still absent. I am certain that this is not a case of tabes; but there are, no doubt, changes in the spinal cord simulating those of tabes in a topographical and physiological sense.

4. Those who have wished to dispute the importance of syphilitic infection in the causation of tabes have always made much of the failure of antisyphilitic measures to cure or even to improve tabes. Its failure to do this would not prove much either way, for in very manifest specific diseases in other organs and in the brain itself it is often quite

number of cases of undoubted cerebral and cerebro-spinal

syphilis in which the symptoms characteristic of syphilitic disease have been associated with the Argyll-Robertson pupil

and with a loss of knee-jerks. In two cases, after the re-

of syphilitic infection in the causation of tabes have always made much of the failure of antisyphilitic measures to cure or even to improve tabes. Its failure to do this would not prove much either way, for in very manifest specific diseases in other organs and in the brain itself it is often quite as useless; but Dinkler,\* reporting upon Erb's cases, gives good proof of improvement in fifty-eight per cent. of cases of tabes. Remembering the destructive effect of the ordinary syphilitic process, such a result seems gratifying enough. Such a percentage of improvement will not, I think, surprise those of us who have been in the habit of using vigorous specific treatment in all but the most inveterate cases of tabes.

In private and dispensary practice I have prescribed mercurial and iodide treatment in all cases of tabes which have come under observation at a reasonably early period of the disease. The cardinal symptoms may not have disappeared, but the treatment has a most marked effect upon those symptoms which may be, and I have no doubt often are, due to purely syphilitic lesion. I refer particularly to the ocular palsies, to lightning pains, and to the characteristic gait. I can add to this the optic-nerve atrophy in rare instances.† It is a satisfaction to know that even this most distressing of tabic conditions can be improved, if in its incipiency, by prompt specific treatment.

The temptation is great indeed to dilate upon one's own experience in this special field of neurology, but there would be little gain for you or for me were I to add another stone to a structure that is complete and strong enough as it now stands.

But as soon as we acknowledge syphilis to be the prime cause of tabes dorsualis, our troubles begin in dead earnest, and a number of interesting questions arise that call for response or at least for investigation. Let us take up the clinical inquiry first.

Like general paresis, tabes is a convenient generic term. The greatest number of cases included under these clinical terms are no doubt due to the morbid processes most frequently present in these cases, say in the one set of cases to a leptomeningitis of the convexity with atrophy, and in the other series to a posterior spinal sclerosis;

- \* Read before the American Neurological Association, July, 1893. Explanations of the Plate.—Figs. I, II, III, and IV are reproduced from drawings after specimens. Figs. V and VI are photographic reproductions (in color).
- Fig. I. Cross section of the cervical cord, showing degeneration of the posterior columns and meningeal infiltration (Pal's method, specimen slightly twisted; low power).
- Fig. II. Cross section of the dorsal cord. Fig. III. Cross section of the lumbar cord; both showing degenerated areas (light), thickened meninges, and altered blood-vessels at low power (Pal's method).
- Fig. IV. A portion of the posterior column, with its meningeal covering, showing infiltration of the cord, and changes in the pia mater—more highly magnified (borax-carmin stain).
- Fig. V. A portion of the posterior column of the lumbar cord. Low power. Infiltration of pia (p) and slightly sclerosed tissues.
- Fig. VI. A part of the same more highly magnified; a, typical endarteritis in the midst of degenerated tissue; b, altered blood-vessel cut lengthwise; sclerosis not so marked as at higher levels.

<sup>\*</sup> Berl. kl. Wochenschr., 1893.

<sup>†</sup> Such improvement has been noted in a patient treated in my department at the New York Polyclinic.

but can we during life recognize those cases in which syphilis is not only the actiological factor that it is in most cases of tabes, but in which syphilis is the active morbid process responsible for one or more symptoms? A suspicion which I first expressed four years ago in an article on Disease of the Midbrain Region \* has been growing upon me since—that supposed nuclear troubles may be syphi litic, and also that the cases of tabes beginning with ocular palsies are apt to be cases of cerebro-spinal syphilis. In the light of further experience and observation I am will ing to modify this statement, maintaining merely that in these cases an active syphilitic process-say a specific infiltration at the base-is apt to be associated with a genuine tabic sclerosis or to precede, by an interval of some months or years, the development of a genuine sclerosis Relying upon this argument, I have insisted upon the possibility and probability of improvement in these cases, and in these patients the result of treatment has been most satisfactory. Only a year ago I was consulted by a young man recently married, who presented the symptoms of tabes. A fellow neurologist, who was evidently not so firm a believer as I am in the Erb-Fournier theory, thought that the patient would get along as well under galvano-faradization of the spine and a little iodide as under any other treatment; but the early occurrence of ocular palsies, with Argyll-Robertson pupil and loss of knee-jerks, without other symptoms of importance, made me urge antisyphilitic treatment. Let me simply report the prompt disappearance of the palsy, an improvement in the pupillary reflexes, and great improvement in locomotion, as well as a return of one knee-jerk under Jendrassik's test. These cases of cerebro spinal syphilis simulating tabes can also be recognized by an unusual irregularity of development of the symptoms; they are the cases in which the light reflex is lost in one eye very much earlier than in the other, or while the one is lost the other remains normal for years if not for all time; as in other syphilitic conditions and with other symptoms of syphilis, the pupillary symptoms are subject to great variation; and, above all, if you find that one or both pupils respond neither to light nor during accommodation, however much the other symptoms may point to tabes pure and simple, you may well be suspicious of an active syphilitic

So much for clinical facts. We must now take up the far more important questions of pathology. Have we any evidence that a syphilitic cerebro-spinal lesion has given rise to symptoms which could not be distinguished from true tabes? Have we evidence to prove that the two lesions—those of syphilis and tabes—are frequently associated? And can we prove that the morbid changes of tabes—I mean the widespread sclerosis, the changes in the peripheral nerves, etc.—are directly due to syphilitic infection?

The first two questions can be answered very positively. Hoffman and Kuh,† Dinkler,† and others have reported cases which during life were diagnosticated as cases of tabes which after death were found to be cases of specific

leptomeningitis invading chiefly the posterior horns and columns. I have shown elsewhere \* that this specific meningeal infiltration invades the spinal cord in the majority of cases in the vicinity of the lateral columns; hence the frequency of spastic cases of spinal syphilis; but if it happens to invade the anterior or posterior surfaces, the clinical symptoms will resemble far more closely those of anterior poliomyelitis or of progressive muscular atrophy on the one hand, and of tabes dorsualis on the other. The gradual invasion of the posterior horns and columns, the progress rather than the retrogression of the morbid process, particularly in the absence of active treatment, will lead naturally enough to the development of symptoms very like those of genuine tabes.

The second question—whether we have evidence that an active syphilitic process is associated with a posterior sclerosis—I can answer affirmatively by evidence which I shall now furnish you.

The history of the case I will report briefly, as it was not distinguished in any respect from the ordinary cases of tabes. The patient had served me on several occasions as a typical example of tabes dorsualis in my lectures to the students. There was no more reason to suspect an active syphilitic process in this case than in any other of the hundreds of cases of tabes that one sees.

The patient, L. K., an inmate of the Montefiore Home, aged forty-five years, began to complain, three years and a half previous to my first examination, of excessive pain in the region of the stomach, followed by vomiting, such spells occurring at irregular intervals. The patient stated that no physician seemed able to rélieve him. A physician who saw him about six months after these attacks began examined him more closely and noted very marked ataxia, and a little later another physician made the diagnosis of locomotor ataxia, finding pains in both legs, loss of kneejerks, Argyll-Robertson pupil, gastric crises, and difficulty in micturition.

Two years after the supposed onset of the disease the patient was admitted to the home. There was not the slightest doubt about the diagnosis. He had contracted pupils which responded a little during accommodation, but were insensitive to light; he had gastric crises of distressing intensity at varying intervals, extreme ataxia, marked Romberg symptoms, slowness of sensory conduction, incontinence of urine, and cystitis.

This condition remained about stationary until two months before his death. The ataxia became so marked that he could not stand or walk; the bladder trouble increased, and bedsores developed, from the effects of which the patient died without at any time having shown paralysis or any symptoms but those of tabes pure and simple.

The autopsy was performed by me in the dead of night a few hours after death. I was not allowed to remove anything but the spinal cord. I was anxious to have the cord in order to prepare a series of sections of genuine tabes for class-room demonstration. On opening the dura I was surprised to find a thickened gelatinous mass covering the

<sup>\*</sup> Am. Jour. of the Med. Sci., March, 1891.

<sup>\*</sup> New York Medical Journal, 1891.

pia from the lower cervical to the upper lumbar segments. On the ventral surface there was no trace of this gelatinous mass, but the pia appeared thickened on both surfaces and of leathery consistence. The cord was hardened very carefully in bichromate-of-potassium solution of increasing strength, and innumerable sections were stained by the Weigert and Pal methods and by eosin and Delafield's hæmatoxylin. In this work I had the valuable assistance of my associate, Dr. Alfred Wiener.

The study of the sections (Figs. I-III) and of the drawings which I present will reveal the existence of a diffuse sclerosis of the posterior columns from the lower cervical to the lumbar enlargement. This sclerosis is most marked in the cervical and dorsal segments, and includes the zone of Lissauer. In the lumbar segments the anterior and median portions of the posterior columns are altered but little. A few cells of Clarke's column could be made out only in the lower dorsal segments. The sclerotic tissue differs in no respect from the classical order of spinal sclerosis. You will notice on the Weigert and Pal specimens that only a very few fibers, scattered here and there through the sclerotic area, have taken the stain, showing the usual destruction of nearly all the fibers at this late stage of the disease. No sclerosis or degeneration of fibers has been noticed in any other part of the cross-section of the cord. The anterior gray matter, too, is entirely normal. The one very marked change to be noted most easily on sections from the dorsal and lumbar segments is the widespread meningeal infiltration; the pia is firmly agglutinated with the substance of the spinal cord, more particularly in the region of the posterior and lateral columns. The posterior roots of the dorsal and lumbar segments are distinctly degenerated, and at almost every level changes characteristic of syphilis could be made out in the small blood-vessels lying between the bundles of nerve fibers. These changes were most marked in the lumbar region, in which the sclerosis was developed least. The pia is characterized by an invasion and proliferation of round cells and by very typical changes in its blood-vessels, large and small (Fig. IV). The larger arteries show enormously thickened walls, the lumen of the arteries often being reduced to one third of their normal diameter and completely blocked by clots of blood. The veins are not so distinctly altered. On sections from the lumbar enlargement (Figs. V and VI) diseased arteries can be seen in an area in which relatively few fibers have been destroyed, but the specific process in the pia and in the cord is distinct enough.

In addition to the posterior spinal sclerosis we find, therefore, a syphilitic leptomeningitis invading the cord at various levels and occasionally invading a distinctly sclerotic area; also a very typical specific arteritis. Whether it is an endarteritis or a mesial arteritis can not be determined easily; certain it is, however, that in the majority of the blood-vessels examined the innermost coat has undergone the greatest changes.

I have paid special attention to the relative development of the specific and sclerotic process, with the idea that the condition of the blood-vessels may have a bearing upon the genesis of the sclerotic tissue. But this part of the

inquiry has been rather unsatisfactory, for the sclerotic and specific processes often merge into one another. In the sclerotic area there are very few blood-vessels, and these are so small that the characteristic changes could not be studied with ease. The arteries of the posterior and lateral divisions were distinctly altered, but the anterior spinal artery and the antero-lateral ramifications were subject to changes quite as distinct; yet there was no disease in the areas supplied by these vessels. It will also be observed that the posterior roots and root fibers, with the blood-vessels contiguous to them, are altered, as are the fibers and blood-vessels of the cord itself.

Post-mortem findings demand a rational explanation. It will not do to make more of them than the facts warrant. In this case we have the evidence of a syphilitic process superimposed upon the sclerosis. I believe the sclerosis to have been the first in the field; the specific infiltration is of later date. Inasmuch as it invaded very much the same areas as are occupied by the sclerosis, we can readily understand why this invasion did not give rise to new symptoms. Since the posterior horns and columns were primarily affected, an invasion of the lateral columns was not characterized by the typical symptoms of disease of the lateral columns. The same thing occurs in cases of combined sclerosis-say in ataxic paraplegia-in which disease of the posterior columns either forbids the development of characteristic spastic symptoms or wipes out all clinical proof of lateral-column affection as soon as it (the posterior sclerosis) is in the ascendant.

Whether disease of the blood-vessels preceded the development of the sclerosis can not be answered offhand; it is possible and even probable, although we must not forget that the sclerosis may have been started some time before the first clinical manifestations were in evidence. This very question will repay further inquiry, and I would urge the most rigid examination of the blood-vessels in every case of tabes, but, above all, in cases of tabes with death at an early period of the disease. I must content myself to-day with having furnished post-mortem proof of the coexistence of the syphilitic and sclerotic processes in a case in which the former was not suspected.

We have now reached the third division of our inquiry. Have we any evidence to prove that the table process is due to syphilitic infection?

I believe that I need not insist on the fact that the "tabic process" is not merely a "posterior spinal sclerosis." Even if we do not subscribe to the full to Jendrassik's views \* that tabes is more of a cerebral than a spinal disease, there is enough of truth in his facts and arguments to make tabes a cerebro-spinal disease; but the same is true of dementia paralytica, and the same is unqualifiedly true of syphilis in its effect upon the nervous system.

For the sake of argument, let us suppose the sclerosis of the posterior columns to be the chief seat of the disease. The most advanced views of the anatomy and physiology of the cord, based upon the researches of Flechsig, Lissauer, †

<sup>\*</sup> Arch. f. klin. Med., xliii, 1888.

<sup>†</sup> Arch. f. Psychiat., xvii, p. 377.

and others, have shown the posterior horns and columns, including Lissauer's tract and the bandelettes externes of Charcot, in which the changes of tabes first appear to be, as it were, accessions to the cord, and to represent in the cord, quantitatively and qualitatively, the entrance of posterior root fibers at each level. Instead of describing tabes as a posterior spinal sclerosis, it would be much more correct to call it a degeneration of posterior root fibers as they enter into the gray and white matter of the cord.

Next comes the question whether or not this degeneration is a primary affair. Recent investigations render primary disease of any white fibers of the central nervous system highly improbable. Degeneration occurs only if the influence of the trophic cells is disturbed or cut off. The trophic cells of the motor fibers are supposed to be in the cortex and in the anterior horns of the spinal cord. The trophic cells of the sensory white fibers are situated in the spinal ganglia and in the terminal nerve bodies in the peripheral organs, chiefly the skin and muscles. Marie, in his remarkably lucid lectures on Diseases of the Spinal Cord, thinks that degeneration of the posterior columns would ensue only upon disease of these terminal nerve organs or upon disease of the spinal ganglia. The investigations into the changes in the terminal nerve endings have not yet been made with sufficient detail to warrant any conclusions, and the examinations of the spinal ganglia, as Marie confesses, have been partly negative. But if we accept these physiological views, must we find disease in one of these two ganglionic centers for sensory nerves? I think not. Keeping in mind the analogy with the motor fibers, it is clear that degeneration ensues not only upon disease of the ganglion cells themselves, but upon disease in any part of the motor tract cutting off this trophic influence. Thus descending degeneration follows not only upon disease of the cortical motor areas, but also upon disease in the internal capsule or in any part of the pyramidal tract of the lateral columns, the seat of the disease being, in each instance, at some distance from the trophic cells. Reasoning upon this analogy, ascending degeneration of the white fibers will ensue not only upon disease of the spinal ganglia, but upon a focus of disease between the spinal ganglia and the posterior horns of the spinal cord. This points to the posterior roots and posterior root fibers. Let us also recall that this is the very region in which the effect of disease of the spinal meninges, which is so often due to syphilis, is apt to be first manifested. In this way a relation between the morbid anatomy of syphilis and that of tabes could be explained. This would be an important link in the chain of evidence, but it would lead to the further inquiry whether the syphilitic poison acts through the medium of the blood-vessels, as I think probable, and whether or not the syphilitic virus, the syphilitic toxin, brings about changes in the blood, and whether or not these changes in the blood are the cause of the changes in the walls of the bloodvessels, as would not be unreasonable to suppose upon wellknown physiological principles.

Let me remind you also of Tuczek's ergot tabes, due to the action of a substance which is known to have a powerful influence over the action of the vascular system. To call tabes a post-syphilitic disease, as Strümpell does, to make it dependent upon the action of the latent syphilitic virus, is but the first step toward an accurate explanation of the relation between syphilis and tabes.\* Before we enter upon the realm of pure speculation let us get at all the hard facts, and let us endeavor to prove tangible changes. "Syphilis and tabes" seemed to me to be a very trite subject only a few years ago. As my studies and reflections were continued, I found this field of inquiry a very inviting one, and I trust I have said enough to show that we have but just turned the first post, and have a hard road to travel before we reach the goal of this inquiry.

# LABORATORY INSTRUCTION IN ELEMENTARY COMPARATIVE ANATOMY AND EMBRYOLOGY

WITH LARGE CLASSES OF MEDICAL STUDENTS.

By A. P. OHLMACHER, M.D.,

PROFESSOR OF EMBRYOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO PROFESSOR OF PATHOLOGY, CHICAGO POLICLINIC.

(Prepared for the Section in Anatomy of the First Pan-American Medical Congress.)

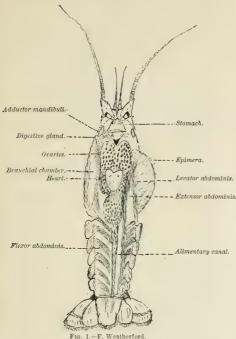

During the past two years I have been engaged in teaching elementary comparative anatomy and elementary embryology to large classes of medical students. In the institution with which I have been connected laboratory instruction in comparative anatomy and embryology has been incorporated into the course of study as two distinct major branches, and each student in the first and second years' course has been expected to pursue the work unless conditioned on account of previous biological training. As a consequence, the classes in these laboratory exercises were large, and my position as a teacher of a compulsory laboratory course in comparative anatomy and embryology in a medical college in the United States, at least, has been a unique one. In the belief that my experience may be of interest to other teachers, I am prompted to bring this subject to your attention and to exhibit to you some samples of class work.

The management of large classes in a biological laboratory exercise involves details, many of which can only be gained by experience. In the first place must come the

<sup>\*</sup> The arguments given above are similar in some respects to those advanced by Dr. Spitzka in his article entitled Return of the Patellar Reflex in Tabes Dorsualis, etc., published in the American Journal of Neurology and Psychiatry, 1884, p. 433. Dr. Spitzka kindly called my attention to his paper, and, while I regret not having been familiar with it before this article was written, I am pleased to think that we have been led to similar conclusions by independent studies.

<sup>†</sup> By a mistake this paper was miscarried and did not obtain a reading at the congress. With the paper were several hundred drawings, made by members of the various classes, which were to be exhibited when the paper was read. The illustrations which accompany this article are photographic reproductions of a few of the drawings, and represent a fair average of the character of the work displayed in the whole set returned by the students. The original drawings were on sheets of paper 11 × 8½-inches, and are of course reduced in reproduction. It must be remembered that, with all their advantages, the photoengravings can not do justice to the original drawings.

laboratory itself and the laboratory equipment. In the college in which I have been teaching the laboratory of comparative anatomy and the laboratory of embryology

occupy two distinct floors of the laboratory building. Each laboratory room is twenty-five feet wide and one hundred and sixty feet long, and well lighted on the side. The room contains fourteen tiers of desks, each tier consisting of eight single desks arranged in two rows of four each, back to back. It will thus be seen that the laboratory of comparative anatomy, for instance, contains desk room for the accommodation of one hundred and twelve students at a single laboratory exercise. The desks are made of whitewood with a plain top and of the proper height to permit the student to work in the sitting posture. Each desk has a top surface of two feet by three feet and a half, with ample knee space below and a cupboard on the right side provided with a Yale lock and containing two drawers, in which the individual student's equipment may be readily stored. Sinks with hot and cold water supply are arranged about the laboratory convenient of access.

The equipment of the laboratory is of such a character that each student obtains and keeps in his locker all the material required throughout the course, with the exception of the microscope, microtome, and an occasional special instrument or staining solution. This outfit is obtained at the opening of the term by the student and kept in his desk. Everything required in the prosecution of the workas dissecting instruments, slides and covers, drawing paper, pen, ink, pencils, etc.-is furnished in the student's outfit. outlined. The animals chosen for study during the first

The microscopes, microtomes, and imbedding baths are kept in the microscope room adjoining the laboratory, and are obtained by the student before entering the laboratory. Each student is provided with a microscope for his individual use. Naturally the equipment of a laboratory in which one hundred students can work during a single exercise, and each student be enabled to prosecute the work independently, involved the necessity of a simple and still complete working outfit. The outfit must be simple and inexpensive as possible, because the multiplication of parts makes the matter of cost a formidable one in fitting out a laboratory on such an elaborate scale. In both the laboratory of comparative anatomy and the laboratory of embryology each one of our students was provided with a simple outfit, sufficiently complete, however, to permit him to carry on independently all the technical work involved in the study.

The text-books which we have employed in comparative anatomy are Huxley and Martin's Elementary Practical Biology, last edition, and Martin and Moale's Dissection of a Rodent.

The character of these invaluable laboratory guides is too well known to every biologist to need a detailed description. The laboratory exercises in these works are systematically arranged, and full technical directions are given, so that the work of both teacher and student is

parative anatomy by the first year's class was ten hours a week; that is, four laboratory exercises of two hours each and one oral exercise.

dents during the winter course of 1892-'93, and twelve students during the spring course of 1892-'93. Gentlemen who had completed a biological course in any of our colleges were exempt from the work in comparative anatomy. Of the students composing our classes, five per cent. were

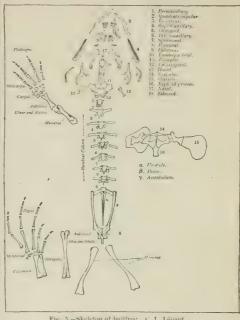

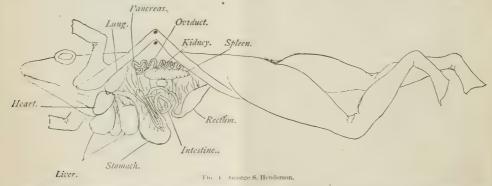

Fig. 5,-Skeleton of bullfrog. C. L. Lénard.

college graduates, ten per cent. were high-school graduates, and the balance were students who had been admitted to the college on examination, or on the presentation of credentials other than school and college diplomas. In all of these classes not more than half a dozen students had ever taken previous laboratory work in any of the biological sciences. In other words, the classes were untrained in

The class in comparative anatomy numbered twenty | laboratory methods. I believe it is pretty generally understudents during the spring course of 1891-'92, ninety stu- stood among teachers of biology that it is very difficult, if not impossible, to introduce a student into the work laid down in Huxley and Martin's Biology who has not had a previous elementary training. We did not find this to be the case, for our classes were introduced directly into the exercises on the crayfish and frog as laid down in Huxley and Martin, and each student pursued to the most minute detail each of the dissections prescribed in the laboratory work, with the exception of the portion relating

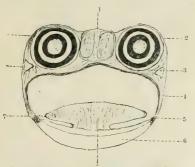

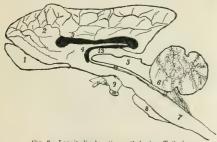

Fig. 6.—Head of frog transverse section. Lee Weber 1. Brain. 2. Eye. 3. Eye musele. 4. Mouth. 5. Jaw bone. 6. Lymph space 7. Tonger. 8. Hyoid.

to histology and embryology. All of the preparations—as, for instance, the wet and dry skeletons, the arterial and venous injections—were made by each member of the class.

It will be recalled that the laboratory work on the crayfish, as laid down by the new edition of Huxley and Martin, occupies about fifty closely printed pages; that upon the frog about one hundred and forty pages; and the dissection of a rat, as prescribed by Martin and Moale, occupies seventy pages. It was our constant endeavor to im-

r. 7.—Longitudinal section, rat's brain. T. Sachs.
 olfactory lube: 2, cerebral bemisphere: 3, corpus callosum; 4, fornix; 5, corpora quadrigemina; 6, cerebellum; 7, medulla; 8, pons; 9, infundibulum; 10, pitutiary body; 11, lamina terminalis; 12, tuber cincroum; 13, third ventricle; 14, iter; 15, fourth ventricle; 16, chorioid plaxus.

press upon the student the desirability of a detailed study of the types selected, in the belief that a training of this kind was more valuable to the medical student than the cursory examination of a number of types.

Especial stress was laid upon the drawings, and we look with pride upon the work which the students have turned out in this direction. It is well known that the laboratory guides mentioned have no illustrations. Aside from this,

the students were discouraged from looking for illustrated works to guide them in their drawing. I can safely assert that, among all of the students who have thus far taken the work in comparative anatomy and embryology, not more than half a dozen members of these classes possessed or referred to pictures of the objects of their drawings. While every legitimate aid, as instruction by the teachers and reference to meritorious work of other students, was given to the members of the class, copying was discouraged and individuality encouraged. The rough drawings of a given object or dissection were first made in a note-book with pencil during the laboratory hour. These rough drawings were inspected by the demonstrator and directions for improvement often given. Each member of the class was provided with fifty or a hundred sheets of heavy white paper, eight inches and a half by eleven inches in dimensions, and one heavily ruled sheet which was placed under the drawing to outline the field. A set of lithographer's pens and a bottle of India ink was also furnished in the student's outfit. The student was instructed to reproduce his note-book drawings in ink on the sheets provided, improving on the original in every possible manner.

Fig. 8 -Ovary of the salamander (resting stage). H. Hartung.

I have the pleasure of submitting for your inspection some of the many hundreds of drawings which have been returned by the students in the laboratories of comparative anatomy and embryology during the last year. Permit me to say that these drawings represent only a fair average, no effort having been made to select the better productions. They represent two or three samples of the work of about a hundred students. Further, I would say that no member of either of the laboratory classes failed to submit a set of drawings representing his laboratory work, for the drawing was considered an essential feature in determining the grade of the laboratory work. While on the subject of drawings it may be said that we invariably noticed that the best students in the laboratory-that is, the most careful dissectors and most enthusiastic workers-made the best drawings. An examination of these drawings will give an idea of the subjects studied during the course, and of the various dissections and preparations made by the students. As a rule, the drawings were made in plain outline, the student being advised to confine himself to outline work unless especially trained in shading. It will be noticed that while the parts of a given drawing are indicated in some drawings were accompanied by a set of notes, usually written on the same paper as employed in the drawings, and often the drawings were described in these notes.

I have before remarked that the animals chosen for study were the crayfish and frog for the first two classes, and the frog and rat for the last class. We have decided upon the frog and rat as the types for study during our future courses, because of the manifest preference of our students for those types which most nearly approach in structure the higher and more familiar mammals. The frog and rat are especially chosen for several reasons. They

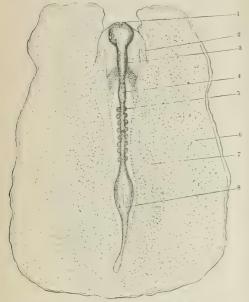

Fig. 9.—Thirty-four hours' chick, C. W. Dulin.

are abundant and easily obtained. They are small and consequently easily preserved between the laboratory hours. I am further much in favor of these smaller animals because the more delicate dissections and acute observations required in their study afford, to my mind, a more valuable discipline and a better preparation for the study of human anatomy than could be obtained by the use of larger animals. Finally, we have two most excellent laboratory guides for the study of the frog and rat.

Our object in introducing the study of the crayfish into the work was to acquaint the student with the anatomy of a typical segmented invertebrate as a means of comparison with the vertebrata. I must confess, however, that the students showed a marked dislike for their work on the crayfish and a corresponding preference for the study of the frog. This was in part due to the fact that they were studying human anatomy simultaneously with their course in comparative anatomy, and their constant endeavor seemed to be to find something in their lower animals which they

could compare with their human dissection. Many of the well-intended lessons on the comparative anatomy of a typical vertebrate and invertebrate animal were therefore

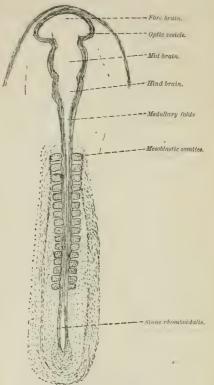

Fig. 10.-Thirty-six hours' chick. B. Feltenstein

lost; but this was compensated for by the interest and en thusiasm displayed by the class during their work on the frog and rat.

The only addition to the regular work was attempted last winter, when about twenty members of the class undertook an extra month's work after having completed the regular course on the crayfish and frog. As a subject for this work I chose the comparative anatomy of three verte-

Fig. 11 - Thirty-six hours' chick, behind heart. S. J. Somberger.

brate brains, permitting the student to select three brains from the animals suggested. The animals chosen for this study were the frog, turtle, fish, snake, bird (pigeon, hen, turkey), rat, cat, dog, sheep, calf, and man. Each student obtained his own material, made his own dissections, and preserved the specimens. The work was undertaken with the greatest enthusiasm, and, considering the short time

left for the study and its occurrence at the end of the col- exercises were held, aside from the oral instruction in the

lege year's work, with examinations coming, I think the laboratory. In fact, as the practical work progressed, results were very commendable. Some of the drawings many questions were presented to the students' minds

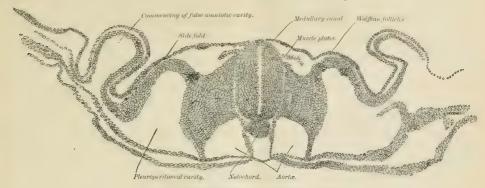

Fig. 12. -- Forty-eight hours' chick, behind heart. H Wagner.

returned by these students are included in those submitted | which called for answers more elaborate than could be for inspection. At the completion of this work every member of the class wrote an essay on the three brains studied as a part of his final examination.

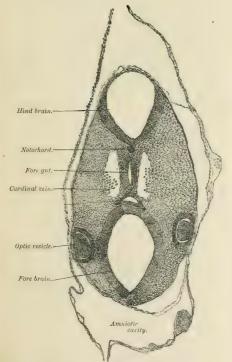

Fig. 13.—Three days' chick, head. I. B. Scagly.

While the laboratory instruction formed the major part of the course in comparative anatomy, some didactic

given in the short laboratory hour. Once every week an oral recitation was held. I say recitation, because our exercises were of a general conversational character, with none of the usual lecture element. The students were free to question the teacher in any subject which occurred to them relating to the work. In these oral exercises the constant aim was to encourage the comparative method of study, and to impress upon the student the relation of his little work to the vast field of animal morphology. Great stress also was laid on the employment of a precise biological terminology, for it is an unfortunate fact that a desirable nomenclature has not yet found its way into human anatomy. From the papers which were returned at the final examinations, it appeared that these oral exercises had not been without their effect in supplementing the laboratory studies.

The course in elementary embryology was conducted upon the same essential plan as that in comparative anatomy. There were laboratory exercises and one recitation a week. In embryology, however, the course was shorter, as only two exercises of two hours each were devoted to the laboratory work in this branch.

The first class in embryology numbered about sixty-five students who were absolutely untrained in laboratory methods, since this course was given when laboratory work was first initiated in the college, and before the new laboratories were built. The first class was divided into two sections, each section meeting but once in two weeks. The second class in embryology numbered about one hundred students, all of whom were accommodated in the new laboratory at one exercise. The third class was the spring class of the present year, numbering about thirty-five students. The second class was somewhat familiar with laboratory technique, most of the students having done some work before coming to the embryology. The last class in embryology was composed of the students who had taken the full first year's laboratory course, including comparative anatomy, during the previous term.

The work of this class was particularly gratifying to me, for more work and better work was accomplished in a shorter time than with any other class, and the enthusiasm which pervaded the class, and the eagerness for more work, were more manifest than during any previous course. This demonstrated most forcibly the effects of systematic laboratory training in elementary comparative anatomy and histology, in providing the student with an independent mastery of laboratory technique, and in developing in him a love of an advanced practical study.

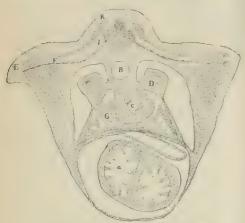

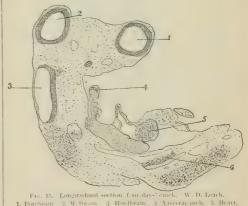

Fig. 14. Five days' chick, through heart. Louis Dysart

Our work in embryology was essentially limited to a study of the chick's development during the first five days of incubation. During the last course some work was done in mammalian embryology. Essentially, the exercise consisted of the practical studies as laid down in the appendix of Foster and Balfour's Elements of Embryology. The students were not, however, provided with this text-book, but were guided in their laboratory exercises by some written syllabi; and for a didactic study they employed any of their anatomical or physiological text-books in conjunction with the oral instruction. During the last year three most excellent text-books on embryology have been made available in our language; and I have recommended one of these three works-by Marshall, Minot, or Hertwig-to my last class as a text-book to supplement the laboratory instruction.

The student prosecuted all of the technical work in embryology. Each student studied the whole living embryo in the egg during the various typical stages of devel opment advised by Foster and Balfour, then removed the embryo and studied it as a transparent object, and finally killed and fixed it and preserved it for future microscopical study. When the series of whole embryos had been studied, the tissue obtained by each student was stained, imbedded, cut in serial sections, and mounted. Every student in the class obtained a thorough drill in the technique of avian embryology, and made many permanent preparations for his future study. For the regular course, how-

ever, it was found advisable not to depend upon the sections cut by the students for systematic study, because many accidents in preparation occurred which would have defeated any plans in this direction. For the systematic study of sections, therefore, the class was provided with a set of uniform sections prepared by the demonstrator.

I have found it advisable, in some minor details, to depart from the order of the practical work laid down in Foster and Balfour. For instance, it was found after the first trial that the thirty-six-hours' chick was too difficult an object for introductory study by students unfamiliar with embryological technique; and, as a consequence, the lessons on the thirty-six-hours' and forty-eight-hours' chicks were unprofitable. I have found, moreover, that much of the success of a laboratory course of instruction depends upon arousing the enthusiasm and interest of the class early in the study, and that three or four unprofitable and difficult lessons at the outset will do much to dampen the ardor of the most earnest student. To make the work interesting early in the course, and to provide the student with an object which he could readily study, I have, during the last two courses, introduced at the second lesson the embryo of the fourth day of incubation. The first lesson was devoted to the study of the unincubated hen's egg, in order that the student might become familiar with the parts of the egg as an introduction to further study, and also that this object might serve as a lesson on an animal ovum, directing the student's thought in the direction of a comparative study of animal ova. The four-days' whole embryo, introduced at the second lesson, proved a most attractive object to the student. The blastoderm was of a sufficient size to permit of careful study by the unaided eye, and the embryo, with its beating heart and welldefined outline, was a very impressive object. The obser-

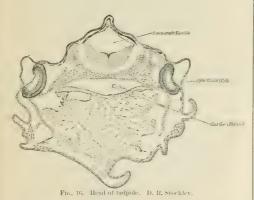

ied, the tissue obtained by each student was stained, imbedded, cut in serial sections, and mounted. Every student in the class obtained a thorough drill in the technique of avian embryology, and made many permanent preparations for his future study. For the regular course, howtroduced, one at each succeeding lesson. One lesson was

6. Kidney.

devoted to a study of the development of the blood and blood vascular system. Following these lessons, several hours were devoted to practical work in cutting and mounting the embryos previously hardened by the members of the class. The study of sections succeeded the technical work, and in this study the order employed with the whole objects was reversed; that is, the younger embryos were studied first. A section behind the heart of a thirty-sixhours' chick introduced the work on sections, and this lesson acquainted the student with the embryonic lavers, the neural canal, notochord, aortæ, Wolffian ducts, cleavage of the mesoblast, etc.-that is, with the fundamental structures of the embryo. Sections through the heart and head of the thirty-six-hours' chick were now introduced, and these followed by various typical sections of the twodays', three-days', four-days', and five-days' chick em-

The drawings were made by the members of the class in embryology in essentially the same manner as in comparative anatomy—that is, class-room sketches were reproduced in India ink. The drawings which have been submitted for your inspection represent a fair average of the work of the last two classes.

My experience in the two years of teaching these courses in a medical school has convinced me of the value of this kind of training in the medical curriculum. In fact, it seems to me an indispensable preparation for the more applied branches of medical science; and, as an introduction to the higher laboratory courses of the medical school, I can conceive of no more profitable work than this elementary training in biology. It is often argued that the student should have obtained his training in comparative anatomy and embryology before entering the medical school. This is certainly true; but how many of the students who apply to-day for admission to our American medical colleges have had a biological laboratory training We are always ready and willing to condition those students who have prosecuted biological studies at any of our science schools.

As to the direct benefits to the student of such a laboratory course as I have outlined, I may mention a few

which have come under my notice during the experience with the classes in the laboratory. The training in the laboratory methods, and the instillation of that independence so essential in practical scientific study, I regard as the first result of this work. The delicate manipulations and patient endeavors required in many of the minute dissections in comparative anatomy are an invaluable discipline to the medical student. The handling of fresh tissue and the often unconscious acquaintance with many simple physiological processes are peculiar to this work on the lower animals. The methods of recording observations, both in writing and in drawing, are early acquired by the student. Scarcely second in importance to the purely technical training comes the training in biological terminology acquired by the students in these branches. It was very gratifying to find, in the various examinations, the ease with which the students had acquired and employed the precise terms of the new biology. Any one who has inspected the anatomical examination papers of the ordinary medical student must have been struck by the student's poverty in this direction.

The verdicts of my colleagues who are engaged in teaching such subjects as histology, pathology, surgical pathology, and bacteriology in the laboratory, are very much in favor of those students who have completed the course in comparative anatomy and embryology. These students enter the advanced laboratory studies with a foundation in the method of scientific work amply sufficient to take from their teachers the time-consuming task of preliminary training in technique; they enter the laboratory with the eager enthusiasm of the true scientific spirit, and their work is accordingly satisfactory. During our last spring course the class in bacteriology, under the instruction of Dr. Gehrman, was composed of the same members as my class in embryology-that is, of students who had taken a year's laboratory work in histology and comparative anatomy. I am informed that the work of this class in bacteriology was of the highest order, and that, while the course of study was shorter than usual, the ground covered by these students was more extensive and the results more satisfactory than with any previous class. Is it too much to believe that these same students will do equally meritorious work in medicine and surgery?

I must take this opportunity of thanking those members of the various classes who have worked so conscientiously and patiently with me, and to express my gratitude to my able assistants who have taken many burdens from the work. Especially do I feel indebted to my friend and colleague Professor Bayard Holmes, whose energy and perseverance have inaugurated this new work in medical education in the face of many obstacles, and whose constant encouragement has helped me through many difficulties.

The Paris Faculty of Medicine.—We learn from the British Medical Journal that Dr. Landouzy has been appointed professor of internal medicine and therapeutics, in place of Professor Hayem.

# THE MILIARIA GROUP.\* By S. POLLITZER, A.M., M.D.

BESNIER and Doyon, in a note to their translation of Kaposi's Treatise, remark that our knowledge of the sweat glands as compared, for instance, with that of the sebaceous glands is very deficient. It is not difficult to account for this fact when we consider the obstacles which the location of the chief portion of the gland, deep in the cutis, creates; that the great number and close relations of the glands make it impossible to observe clinically the beginning of a disorder in a single gland; and, finally, that the early involvement of the neighboring cutis in most cases entirely obscures the relation of the sweat gland to the pathological process. There is no reason, however, to believe that the sweat glands are favored with any special immunity from the disorders to which all glandular structures are subject. It is nearly thirty years since Hebra ! wrote that up to that time no diseases of the sweat glands involving structural changes had been described, and since that time not much has been added to our knowledge. The host of young dermatologists, however, in the great medical centers who are subjecting all the diseases of the skin, the common not less than the rare, to a rigorous microscopical study and the improved methods of examination, augur well for our progress in this special department not less than in the whole field of dermatology.

To review for a moment the organic diseases of the sweat glands which have already been described: It was my good fortune to be the first to establish as a disease of the sweat glands,# on the sure footing of pathological anatomy, a disorder which the keen eye of the great French clinician Verneuil had led him to locate in the sweat glands and which he called, on purely clinical grounds, "hidrosadénite phlegmoneuse," and the papers of Dubreuilh have corroborated my results. At the present time there exists some confusion as to the pathological relations of adenoma of the sweat glands. Darier and Jacquet's "hydradénomes éruptifs" and "adénomes sudoripares," Török's "syringo-cystadenoma," Perry's "adenoma of the sweat glands," Quinquand's "cellulome epithélial éruptif kystique," etc., describe conditions which have been referred to the sweat glands, but many of them, we know now, are independent of these structures; in fact, with the exception of two or three cases in which a true adenomatous proliferation was found disguised under other clinical conditions, | no undoubted case of this form of tumor has been described. These benign epithelial growths of the skin are being now vigorously studied, and we may soon hope for fuller light on the subject. It appears certain that malignant (cancerous) growths may originate in the sweat glands; and when we have added atrophy, hypertrophy, and fatty degeneration of these structures we have almost exhausted

the brief register of the organic diseases of the sweat glands. There remains only the group which forms the subject of this paper.

I propose to group together three disorders of the sweatgland apparatus which depend on an obstruction to the flow of sweat through the duct. The term miliaria is now used to designate an eruption of minute vesicles or papules with clear or cloudy contents, associated with excessive sweating; and the various terms sudamina, miliaria crystallina, miliaria rubra, miliaria alba, miliaria vesiculosa, miliaria papulosa, and lichen tropicus have been applied to two distinct disorders, sometimes indiscriminately.

Miliaria crystallina or sudamina consists of an eruption of perfectly clear transparent vesicles, from a pin's head to a split pea in size, that develop anywhere on the body in the course of some general febrile disease (articular rheumatism, puerperal fever, typhoid, etc.). They have been aptly described as resembling drops of dew scattered over the surface. They are accompanied by no subjective symptoms whatever, are of brief duration, and their disappearance is followed by but slight desquamation. The eruption is entirely without diagnostic or prognostic value on the disease with which it is associated.

The anatomy of the vesicle has been studied by Haight, Robinson, and Török. They agree that the vesicle is located wholly in the horny layer of the epidermis and that a sweat-gland duct may generally be demonstrated leading into it. The vesicle depends on an obstruction to the outflow of sweat, which, unable to escape, distends the tissues below the point of obstruction. This obstruction must be located in the uppermost layers of the stratum cornuum, if not in the very surface of the integument. Haight's theory of the cause of the development of this vesicle was that in a sudden outflow of sweat the current forced one turn of the spiral duct against another, forming a valvular occlusion. This view, it seems to me, is not tenable; such an occlusion would naturally take place at the first spiral turn in the course of the sweat current, and not at the last. The vesicle would therefore be located at the bottom of the rete and not at the top of the horny layer. A more reasonable explanation, it appears to me, is that in the neglect to which the skin is necessarily subjected during the anhidrotic stage of the fever in connection with which the rash occurs, the orifices of the sweat ducts become blocked up by epidermic debris, and nutrition changes in the epidermis, due to the fever, may aid in producing this effect. The fluid, when the perspiration is restored in the "critical sweat," can not pass the obstruction in the surface and distends the tissues just below the point of occlusion.

In miliaria rubra—called also lichen tropicus, miliaria vesiculosa, miliaria papulosa, miliaria alba, eczema sudamen, and prickly heat—the seat of the lesion is somewhat deeper. The affection is too well known to require more than a few words as to its clinical appearance. It consists of minute vesicles or papules on a slightly reddened skin which itches and prickles intensely. The contents of the older vesicles are sometimes cloudy or opaque and they have a whitish appearance; hence the term miliaria alba. Aside from the evidence afforded by the histological examination, the clin-

ical appearances and the course of the disease alone negative the view of the Vienna school that miliaria rubra is an eczema. No eczema will remain for weeks in the erythematous-vesicular stage without weeping, and no eczema will disappear as does prickly heat, sometimes within twenty-four hours, leaving hardly a trace. I have before me many gentlemen who come from tropical countries and who have large experience with prickly heat; it can not be necessary to dwell on the manifest differences between an eczema and this disease.

The anatomy of miliaria rubra has been studied by Robinson, Török, and myself. Robinson regards the affection as an eczema; Török looks upon it as due to sweating,

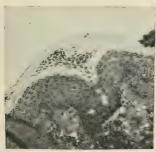

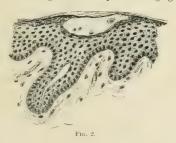

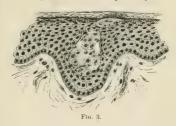

Fig. 1.

but the vesicles are not, according to him, associated with the sweat ducts. My own observations, published in the Journal of Cutaneous and Genito-urinary Diseases, February, 1893, were based on the histological study of eight cases in different stages and from patients ranging in age

from the infant to the adult. I reported in that paper that I had found the vesicles to be always connected with the sweat ducts, but subsequent studies on other cases lead me to modify this statement somewhat. I agree with Török that the vesicles are sometimes the result of inflammatory colliquative changes in the epidermis, but believe this form of vesicle to be the exception, and to occur only in cases attended with a great deal of irritation. The characteristic vesicles are always found in or below the stratum granulosum, but the entire sweat canal in the epidermis is often distended with fluid below this point, forming a funnel-shaped spiral canal. Serial sections are necessary in many cases to enable the observer to determine with cer-

tainty the relation of the sweat gland to the vesicle. The contents of the vesicles—which it would be correct, in some respects, to call cysts—are at first perfectly clear (Fig. 2);

later they become filled with cellular elements (Fig. 3), and the spaces are sometimes occupied by a compact mass of granular elements and epithelial detritus (Fig. 4). It is in this stage that they clinically resemble papules, though a minute vesicle deep in the epidermis will also give the appearance of a papule. Otherwise the only histological appearance to account for the clinical picture of the minute papules which have given the name of miliaria papulosa or lichen tropicus to the affection consists in a minute circumscribed thickening of the horny layer at the orifice of the sweat duct, as is shown in Fig. 1. There is in the cutis only a slight

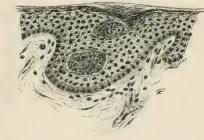

Fig. 4.

amount of circumvascular infiltration, but here and there the emigration of white blood-corpuscles in the papillary layer is very considerable, and it is above such patches that vesicles of colliquative origin sometimes appear. This evidence of inflammation is only natural when we consider the great strain on the papillary blood-vessels and the vasomotor nerves due to the heat and the added effect of the irritation from the blocked-up sweat ducts.

We have no positive data for an explanation of the blocking up of the ducts while sweating is so active as in those who acquire prickly heat. In my publication \* on this disease I have advanced a theory to account for this phenomenon. The horny layer, bathed constantly in sweat, becomes saturated with watery fluid, and the cells, swelling by imbibition, occupy more space vertically and laterally, and thus spread over the orifices of the sweat ducts, occluding them at a moment when the flow of sweat is temporarily in abeyance. The next flow of sweat meets the obstruction in

the horny layer, and, unable to escape, distends the epider mis first of all just below the point of obstruction-that is, below the lowest layers of the horny layer-and later, as the amount of secreted fluid increases, the distention involves the entire canal in the epidermis. That such a swelling of the cells of the horny layer actually occurs, I have demonstrated in the paper referred to. The saturation with fluid may be so great and so constant that the horny layer in the neighborhood of the sweat pore assumes something of the appearance of that of a musous membrane; its nuclei are well preserved, and take nuclear stains readily. (See Fig. 1.) We must still, however, account for the fact that although all persons sweat in hot weather, not everybody acquires prickly heat, or, to express it in the terms of my theory of the pathology of the disease, not every horny layer imbibes the water of the perspiration and swells. To explain this difference in the behavior of different horny layers under apparently similar conditions, I have taken into account a factor which we know differs in different individuals and in different parts of the skin in the same individual-that is, the different degrees to which the skin is normally supplied with fat. Horny cells impregnated with fat can not absorb water, and therefore will not swell up and occlude the sweat ducts. Natives of tropical countries have, we know, particularly well-oiled skins, and are for this reason but little subject to prickly heat, while the inhabitant of a temperate climate resident in the tropics, who perhaps, like the Englishman in India, takes his daily bath or two, suffers intensely from this affection. No portion of the integument sweats more abundantly than the face, where prickly heat practically never occurs; the face is better supplied with fat than any other region. There is a therapeutic hint in this theory which I should like to suggest to some of my confrères from the South. It is to prevent the imbibition of water on the part of the horny layer before the disease develops in those who are subject to it, by providing an abundant supply of fat by means of inunctions with some fatty body. Of course, after the disease has once developed, soothing applications, especially powders, are indicated.

Miliaria profunda is a disease which was first described by Robinson \* in 1884, and which until very recently remained without a name. It is true that Jackson,\* in 1886, described the disease under the name of "dysidrosis of the face," from a fancied resemblance to the disease of that name, affecting the hands, described by Tilbury Fox and Hutchinson; but aside from the fact that the existence of Fox's dysidrosis as a disease of the sweat appa ratus is still sub judice, the resemblance between our disease and Fox's is so remote that Jackson's name was generally received with great reserve. A case of the disease has been described by Rosenberg, of Berlin, and Hallopeau, of Paris. I have seen several cases, and Robinson, in a recent paper, says that he has seen perhaps forty cases in the last eight or nine years. The rash consists of nodules of a translucent boiled sago-grain appearance, from a pin's head to a pea in size, located in the face, especially around the nose, on the cheeks and forehead. It is most common in middle-aged women, though I have seen it in children and adolescents. The nodules undergo no change after they have once formed so long as the weather remains warm, but on the approach of winter they slowly disappear, to recur again the following summer. If they are incised, a drop of perfectly clear watery fluid escapes. They occasion no subjective symptoms whatever.

The anatomy of the disease has been studied by Robinson and by myself. The conditions are very simple. There are no changes—except, perhaps, those due to pressure—in the epidermis. The corium is occupied by a cyst of clear contents whose walls consist of a double layer of epithelial cells on a basement membrane (Fig. 5). The coil glands

show no changes except sometimes an increase in the width of their lumen. The condition is clearly one of cystic dilatation of the sweat duct, the dilatation occupying the corium, and the obstruction on which it depends must therefore lie below the epidermis. Given such an obstruction, the secreted sweat must distend the canal through which it can not escape. With the approach of cold weather and the cessation of sweating, the sweat in the cyst is absorbed and the lesion apparently disappears; on the re-establishment of the sweating the following summer the affected duct is again distended by the secreted fluid. Since the obstruction lies in the corium, it is not desquanated with the epidermis, and the condition is therefore permanent.

When this paper was planned the disease had received no name except that of dysidrosis-a term to which there were manifest objections. In the last number of the Journal of Cutaneous and Genito-urinary Diseases (August, 1893) Dr. Robinson has a paper on this disease to which he now gives the name hidrocystoma. The name is certainly appropriate in that it conveys a fair idea of the pathological condition. I see, however, no reason to modify my suggestion as to the name miliaria profunda. The aim of this paper is to emphasize the fact that there is a group of diseases of the sweat glands which have as a common feature the occlusion of the duct of the gland without injury to the secreting coil. There results, therefore, in all a kind of retention cyst. In the first, or superficial miliaria (miliaria crystallina), the obstruction is in the uppermost layer of the stratum corneum; in the second variety (miliaria media, or rubra) the obstruction is in the lower horny layer just above the level of the stratum granulosum; in the third, miliaria profunda (hidrocystoma, Robinson), the ob-

<sup>\*</sup> Journal of Cutaneous and Genito-urinary Diseases,

struction is entirely below the epidermis. To two of these conditions the name miliaria has already been given and is sanctioned by long usage. It seemed but natural, therefore, to apply this name to the third disease and thus to include under a common name diseases which are pathologically and atiologically so closely related. There is, of course, a well-grounded objection to the multiplication of names in dermatology; but when its purpose and tendency is the simplification of our knowledge of a group of diseases, it seems to me not only justifiable but a distinct advantage. On this point I should be glad to hear the views of the section.

32 East Sixtieth Street.

#### . TWO CASES OF

### PROGRESSIVE MUSCULAR ATROPHY.

A REPORT OF THE PATHOLOGICAL EXAMINATION, WITH SPECIAL REFERENCE TO THE FUNCTIONS OF CERTAIN CELL GROUPS IN THE SPINAL CORD.\*
BY GRÆME M. HAMMOND, M.D.

Cases of progressive muscular atrophy, particularly when accompanied by pathological investigation, are of sufficient rarity to warrant their presentation. One of my cases is a typical example of the Aran-Duchenne type of the disease, beginning in the muscles of the hand and progressing in the usual manner. The other is a case of the peroneal type—that is to say, progressive muscular atrophy beginning in the peroneal muscles—and must not be confounded with the so-called "peroneal type" of Marie and Tooth. The history of the latter case, up to the time the patient came under my observation, is furnished by Dr. Charles E. Lockwood.

"Mrs. A., white, aged forty-six years, born in Ireland. Family history: Father died of old age; mother died of cancer of the breast, aged sixty-six years; three sisters and one brother living and well; one sister died of consumption, aged twenty-two years.

"Personal History .- Never seriously ill; has suffered some what at times from malaria. In the spring of 1889 she had a sharp, burning, shooting pain in the right foot, but did not consult a physician in regard to it. She spent the summer of 1889 in Saratoga, and thinks the place where she lived was damp. No history of gout, rheumatism, or syphilis. On September 1, 1889, she stumbled over a chair, bruising her right shin slightly, and a few days afterward noticed that she was unable to walk as well as formerly. The trouble persisting, she consulted me February 6, 1890, complaining of a peculiar heaviness and weakness of the right leg and foot in walking, and of a diminution of temperature in these parts. On examination, I discovered marked weakness of the flexors of the foot and the extensors of the toes. The right leg and foot felt colder to the touch than the left; atrophy of the anterior tibial muscles was not marked. There was no pain, no sensory, rectal, or bladder disturbance. Tendon reflex at the right knee was present. There was diminished electro-muscular excitability to the induced current, and the normal formula was practically un-

\* Read before the American Neurological Association, July, 1893.
† Medical Society of the State of New York, Eighty-sixth Annual Meeting.

changed so far as galvanism was concerned. Here, then, was a case characterized by a marked loss of power in the group of muscles supplied by the anterior tibial nerve, coming on insidiously and gradually, with no premonitory symptom except the shooting, burning pain in the right foot noticed during the preceding spring. No appreciable atrophy, no sensory, bladder, or rectal disturbance. Tendon reflex at the knee intact; reaction to the faradaic current diminished, and to galvanic unaltered. The temperature of the affected limb lower subjectively and objectively, and this condition connected in its apparent commencement with a local injury in the mind of the patient, who otherwise appeared to be in a good state of health. Was the affection central or peripheral? I was unable to decide, and asked Dr. Allan McLane Hamilton to see the case. He expressed the opinion that the trouble was not central, advised the application of the actual cautery over the peroneal nerve near the outer tendon of the biceps muscle, the hypodermic injection of the paralyzed muscles with one sixtieth of a grain of strychnine daily, massage, and the daily application of the faradaic current.

"On March 31, 1890, while going to church, the patient's right leg gave way and she fell, bruising her face severely. On April 1, 1890, my patient was seen by Dr. M. Allen Starr, who found paralysis of the anterior tibial group of muscles of the right leg, atrophy, and the reactions of degeneration, loss of faradaic action, and change in the galvanic reaction, with the knee-jerk still preserved."

When I first saw the patient there was complete paralysis of the muscles of the right leg from the knee downward. Inthe thigh the extensor muscles of the leg were almost completely paralyzed. She could contract the quadriceps extensor, but not sufficiently to move the leg. There was a stronger contraction of the flexors. All of the muscles of the leg and thigh were atrophied. This condition was particularly apparent in the vastus internus. In the left leg the condition of the muscles was not quite so bad. She could voluntarily flex and extend the toes, but to a very limited extent. Faint motion could also be seen when attempts were made to flex and extend the foot. The muscles of the thigh were capable of exerting a moderate degree of force. Her left leg was strong enough to enable her to take a few steps about the room with the aid of a pair of crutches. The muscles of the left leg were also atrophied, but less so than those of the right leg.

The knee-jerk was almost imperceptible in the right leg, but was readily obtained in the left leg, although the action of the muscles was extremely sluggish. Sensation was normal in every particular. Tickling the soles of the feet induced an immediate jerk in the left leg and an attempt of the thigh muscles to jerk the right leg. The abdominal reflex was also present. Fibrillary twitchings were frequently seen in the muscles of both limbs.

The right hand and forearm were also involved. The muscles of the thenar and hypothenar eminences were weak and atrophied, and the flexors of the hand were beginning to show signs of weakness. Fibrillary twitchings could also be seen in the muscles below the elbow. The left hand and arm were not affected at all.

None of the muscles of either leg would respond to faradism, but all of them reacted to the galvanic current. Those that were paralyzed and atrophied the most responded the least, but none of the muscles entirely failed to show vitality. Some of the muscles, particularly those of the left leg, reacted better to the C. C. C., while in others the C. C. C. seemed to equal the A. C. C. The muscles of the hand would still respond to strong currents of faradism, and reacted normally to galvanism qualitatively, but were diminished to it quantitatively.

The atrophy of the muscles progressed steadily, and gradually electrical contractility was lost, until at the time of her death the only reactions that could be obtained in the lower limbs were in the extensors of the left leg.

The atrophy in the right arm extended and finally involved the deltoid, biceps, sterno-cleido-mastoid, and trapezius, but these muscles were never completely paralyzed and were but moderately atrophied. The atrophy in the muscles of both hands became extensive, and a short time before her death the strongest galvanic current the patient could bear failed to elicit any muscular response. The flexors and extensors of the right hand were also atrophied and failed to respond to electrical excitation. In the left forearm fairly strong galvanic currents caused moderate but distinct contractions of both flexors and extensors. I wish to call particular attention to this complete paralysis of both hands and one forearm with retention of muscular movements in the other forearm, and will refer to it again in speaking of the preservation of certain cells in the cervical cord and the disappearance of others. The muscles of the back were paralyzed and atrophied so that she could not sit erect.

During the last month of her illness the abdominal muscles, particularly on the right side, became weak and were probably atrophied. The patient observed that she could not make an expulsive abdominal effort at stool, and when she attempted to sit up from a recumbent posture the hands placed upon the abdominal muscles would fail to feel the muscles on the right side of the abdomen contract, while those on the left side contracted fairly well. The intercostal muscles on the right side were also affected. About a week before she died she began to complain of shortness of breath and attacks of cardiac palpitation. There was also feebleness of voice and difficulty in swallowing. At the end of the week she suddenly had an attack of either cardiac or respiratory paralysis. She rallied from this after prompt and energetic treatment. Two hours later she had another and similar attack, from which she died. I performed the autopsy about ten hours after death. I removed the cord and brain and such pieces of nerves as I could obtain near the cord. The family of the patient objected to the proceedings and stopped me before I could get any of the muscular tissue and large nerves.

The specimens were hardened in Müller's fluid and stained after Weigert's method. The posterior white columns of the cord were normal from their origin to their termination in the nuclei gracilis and cuneati, and beyond this point nothing abnormal could be discovered in the sensory area of the medulla or pons. The posterior horns of gray matter were also normal, and Clark's columns were well developed, the cells standing out sharply in direct contrast to those observed in the anterior horns. The direct cerebellar tract seems in the majority of sections to be well preserved. In other sections there seems to be more connective tissue than there should be, but the nerve tubes are distinct and their axis cylinders stain plainly. Gowers's column is degenerated throughout its entire extent. There is a great increase of connective tissue, many of the nerve tubes have disappeared, and numbers of those fibers which remain appear degenerated. The direct and crossed pyramidal tracts show greater degenerative changes than any of the other white columns. Normal, healthy fibers in these regions are comparatively scarce. The whole of these areas seems to be occupied by a dense mass of connective tissue through which disorganized nerve tubes are sparsely scattered. Comparing these regions with the normal posterior columns, a most perfect contrast is seen. (See illustrations.) It is in these pyramidal tracts and in the anterior horns of gray matter that the most striking changes are seen. The sclerosis of the pyramidal tracts can be traced upward in successive sections, and is intense at all levels until the

upper cervical region is reached. Here the sclerosis begins to fade, and by the time the motor decussation is reached has disappeared completely. The pyramids throughout the medulla and pons appear normal.

In the anterior horns most of the nerve cells have disappeared and those that remain are greatly degenerated. I do not believe, in a careful examination of a great many sections, that I have observed one perfectly normal cell. Those that remain are rounded, have lost their processes, their nuclei areindistinct, and the body of the cell is granular. There is a distinct degeneration of the anterior-root fibers passing from the anterior horn through the anterior and lateral columns. Occasionally a fiber may be seen which presents a fairly normalcondition, but frequently whole fasciculi appear to be replaced by fibrous tissue: The fibers in the anterior commissure seemed, with those in the posterior commissure, to be in a very fair state of preservation, and many of the former can be traced for quite a distance into one anterior horn, presumably the left one, while on the other side they end with the commissure. The interstitial tissue of the cornua is changed. The nerve fibrillæ are entirely gone from one horn and greatly diminished in the other. There is an increase in connective tissue and connective-tissue cells. The blood-vessels are dilated and their walls considerably thickened. The cornua have changed somewhat in shape, the change being more marked upon one side than upon the other. In the lumbar and sacral regions both anterior horns are less voluminous than they should be. but both are very much slike. In the dorsal region one anterior horn is shorter than the other, and the lateral horn on that side is less prominent than the one on the opposite side. In the lower cervical region a marked difference in the horns isobserved. On one side the medial, ventral, and lateral projections are fairly well marked, while on the other side the twoformer divisions have disappeared. Still higher in the cervical

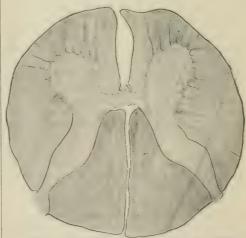

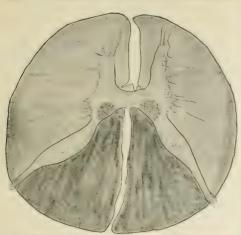

Fig. 1.—Case I. Lumbar cord, third segment, showing the position of the cells which probably supplied the quadriceps extensor cruris group. The posterior columns and the white substance in contact with the anterior horns are normal (dark shading). All else is degenerated.

region the anterior horns are more symmetrical, while at a higher level still both horns are alike. In the sacral cord no cells were found at all. In the lumbar cord (at the level of the second and third nerves) a few cells are observed on the lateral side of the horn on one side; no cells are found on the other

side (Fig. 1). In the dorsal region the cells are more numerous, but one side still shows a marked numerical advantage over the other. In the anterior and lateral horns a few cells can be

Fro. 2.—Çase II. Dorsal region, tenth segment, showing position of the cells which probably supplied the abdominal muscles. Dark shading indicates normal tissue.

seen, while upon the opposite side they are only occasionally met with (Fig. 2). In the lowest cervical regions the inner or medial group is absent, a few cells of the anterior group are present on one side and absent on the other, and there are a few cells of the lateral group on both sides (Fig. 3). Higher in the cervical region a few cells of the anterior group appear in the horn which did not have any at a lower level.

Tracing the horns upward to the point where they are cut off by the motor decussation, we find that the cells increase numerically, but still show very evident signs of degeneration. Following the cells ttill higher into the medulla, it was observed

Fig. 3.—Case I. Lower cervical region, showing the position of the cells which probably supplied muscles in the forearm. Dark shading indicates normal tissue.

that the cells forming the nucleus ambiguus as high up as the ninth, tenth, and eleventh nerves were rounded, granular, had lost their processes, and their nuclei in many instances were invisible—a similar change to that observed lower down in the cord, only not so well marked. Higher up, where the nucleus ambiguus gives off fibers to the facial nerve, the cells presented a perfectly normal appearance.

There is nothing in the clinical history of this case which separates it from the typical form of progressive muscular atrophy, except that it began in the leg. There is nothing in the pathological findings which distinguishes this case from others.

The disease which is commonly known as the "peroneal type" of progressive muscular atrophy, and which was described almost simultaneously by Marie and Tooth, is an essentially different affection from the one under consideration. That described by Marie and Tooth occurs in young subjects, usually with a family history of a similar disease, and in which there are marked disorders of sensibility. The pathology of this disease is not clearly understood, but it is undoubtedly very different from that of progressive muscular atrophy.

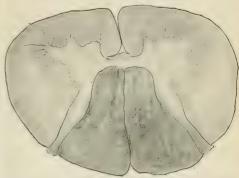

Fig. 4.—Case II. Lower cervical region, showing similarity of appearance to Fig. 3, Case I. Absence of all cells. Dark shading indicates normal tissue.

Gowers\* does not consider such cases to be of spinal origin at all. He considers a peripheral neuritis, motor or total, of extremely chronic course and peculiar origin, must be recognized as the only possible lesion. He quotes a case by Friedreich and another by Gombert to support his opinion. This theory of the pathology was also advocated by Tooth and accepted by Marie. There is therefore no foundation for terming this affection progressive muscular atrophy.

The case under consideration is very different. The changes in the spinal cord are identical with those previously described by other observers and resemble the alterations in the cord in the case about to be reported as closely as one specimen can resemble another. (Compare Figs. 3 and 4.) It can therefore be regarded as a true type of progressive muscular atrophy, while the so-called "peroneal type" of Marie and Tooth has no established right to the title at all, and its employment in such cases is decidedly misleading and confusing.

In regard to the groups of cells observed in certain regions of the cord a word must be said. The relation of cell groups in the anterior horns to individual muscles and groups of muscles has not been by any means definitely determined. It is only by collecting and studying the evidence presented by a great number of cases that anything like scientific ac-

<sup>\*</sup> Dis. Nerv. Syst., Part I, 1892.

curacy can be obtained. Every contribution which pertains to this end is therefore important. In this case certain muscles retained perceptible vitality up to the time of death, while the other muscles were totally paralyzed and greatly atrophied. Certain cells were observed in the cord in a partially degenerated condition, while all other cells had disappeared. The level of the cord at which these partially preserved cells were found corresponds to the level from which the muscles preserving vitality should re ceive their motor power. It is fair to suppose, therefore, that the cells which were observed were the ones which were in direct communication with the muscles which retained voluntary power. In the lower lumbar and sacral regions no cells were observed at all and the horns are both slightly shrunken but symmetrical. This indicates, of course, that in this region both sides of the cord were equally diseased, and in support of this view it was stated that the muscles of both legs below the knees were completely paralyzed and atrophied. But in the left thigh the patient could slightly move the quadriceps extensor, and this group of muscles responded to electricity to the last. In the upper part of the lumbar cord, at the level of the second and third segments, I find sections in which a few cells can be seen in one horn on its lateral aspect (Fig. 1). Probably it was these cells which supplied the quadriceps extensor. In the dorsal region, at the level of the tenth segment, cells were observed in the anterior and lateral horns on one side (Fig. 2). There was during life wellmarked paralysis of the abdominal muscles on one side, with good preservation of the corresponding muscles on the other side. It is probable that these cells were in relation with the preserved abdominal muscles, as the muscles of the back were completely paralyzed, so far as could be ascertained.

In the lower cervical region, at the level of the seventh and eighth segments, the mesial group of cells had disappeared from both horns and the anterior group from one horn (Fig. 3). The muscles of both hands were paralyzed and the muscles of one forearm, both flexors and extensors. The muscles of the other forearm, both flexors and extensors, retained moderate power until death occurred. The conclusions to be drawn from this condition must be that the mesial group supplied the muscles of the hand while the anterior group supplied the muscles of the forearm. It seems probable that the cells supplying flexors and extensors of the same limb are not intermingled, but that one group is superimposed upon the other and are directly contiguous.

The second case was that of a woman, forty-four years of age, whom I first saw in the year 1882. At that time the disease was just beginning and only affected the muscles in the ball of the left thumb. I saw her from time to time until she died, and was therefore able to watch the progress of the disease almost from its incipiency to its termination. It ran the usual course and was in every way typical. Muscle after muscle wasted and became paralyzed. Fibrillary twitchings were well marked. The electrical reactions were normal qualitatively as long as they could be obtained. The contractions were feeble, however, and, gradually declining, finally ceased altogether in the affected muscles. At the time of her death all

of the muscles receiving innervation above the second dorsal nerves, except the facial muscles, were atrophied. Paralysis was almost complete. She could not move either hand or either arm. The humeri had dropped from each glenoid cavity over an inch, and her head rolled about helplessly on her shoulders. She became maniacal and finally died in acute mania apparently from exhaustion. Her legs were not atrophied or paralyzed in the least, but they were slightly spastic. Her gait was perhaps a trille stiff. The reflexes in the lower extremities were slightly exaggerated, but were abolished in the arms. Ankle clonus could not be obtained. There were no disorders of sensibility anywhere. I was only able to obtain the cord and a portion of the medulla.

It is not necessary to detail all the pathological changes found in this cord. Where such changes existed they were identical with those already described in the preceding case. In the cervical region there was the typical absence of cells in the anterior horn, slight alterations in the shape of the horn, and sclerosis of the motor tracts with preservation of the posterior horns and posterior white columns (Fig. 4). In the dorsal and lumbar regions the changes were slight, particularly in the latter, which appeared to be essentially normal.

I have placed sections of the cords of both of these cases under the microscopes so that the members of this association can compare one with the other and observe the conditions as I have stated them.

The microscopical picture which these sections present approaches very nearly the illustrations which Charcot has given us of "amyotrophic lateral selerosis." In that disease we have a combination of the symptoms of progressive muscular atrophy together with those of sclerosis of the lateral pyramidal tracts. In these specimens there is undoubted sclerosis of both crossed and uncrossed pyramidal tracts, yet no symptoms of this condition were evinced during the life of the first patient and were only very slightly marked in the lower extremities of the second. This was probably the result of descending degeneration of the pyramidal columns. There were no symptoms of progressive muscular atrophy in the legs, and the arms never showed any evidence of spasticity.

Gowers states that he has never seen a case of progressive muscular atrophy without accompanying degeneration of the pyramidal tracts. Both of these cases presented that characteristic to a marked degree. The distinguishing feature of amyotrophic lateral sclerosis from progressive muscular atrophy is that symptoms of spasticity precede the atrophy and paralysis. In the latter stages of both diseases they are alike both clinically and from a pathological standpoint. The probability is that in progressive muscular atrophy the initial degeneration begins in the anterior horns of gray matter and the degeneration of the pyramidal tracts occurs subsequently. Spasticity then could not be induced because the motor cells, on the integrity of which spasticity depends, would be degenerated. In amyotrophic lateral sclerosis the degeneration evidently begins in the pyramidal tracts and subsequently extends to the anterior horns. In the late stages of the disease, when the cells in the anterior horns are degenerated, the symptoms of lateral sclerosis-such as clonus, exaggerated reflexes, and rigidity-decline and finally disappear. These two diseases are pathologically identical.

A singular feature in both of these cases was the fact that Gowers's ascending antero-lateral tract was degenerated and yet there were no disorders of sensibility.

Progressive muscular atrophy is a distinct affection depending upon certain and invariable lesions. It therefore seems absurd to classify the disease in "types" as it is now done. There are now four or five different "types" described which derive their titles either from the location of the first signs of atrophy, or from the age of the patient. An individual either has progressive muscular atrophy or he has not, and it should not be a matter of the least importance from a medical standpoint whether the disease begins in the hand or in the foot, or whether the patient is five years old or fifty. It would be neither more nor less absurd to speak of the "hand type" of locomotor ataxia because the disease happened to begin in the upper extremities.

#### THE

# PREVENTION OF SCARLATINAL NEPHRITIS.\* BY WILLIAM H. FLINT, M. D.

In view of the facts that nephritis is the most dreaded sequel of scarlet fever, that its prophylaxis has received comparatively slight attention at the hands of most authors, and that the practice of some contemporary physicians takes little cognizance of this aspect of the treatment of scarlatina, the writer has judged it opportune to present this subject before the Clinical Society, hoping that the narration of his experience in endeavoring to prevent renal disease, and the description by those members of the society who will kindly participate in the discussion of their prophylactic methods, may redound to our advantage and to the benefit of our patients.

The actual dearth of information in medical literature regarding this important matter will be evident to any one who critically reviews the works of the leading authorities to which the growing medical mind is wont to turn for counsel and guidance and which the writer has examined while preparing the present paper. This lack of accurate information, coupled with the fact that renal inflammation is still a frequent complication or sequel/of scarlet fever, goes to show that a careful consideration of the preventive treatment of scarlatinal nephritis is even to-day in no sense a work of therapeutic supererogation.

It is true that most writers upon scarlatina say that the diet during the febrile period of the disease should be light and liquid, and that the patients should for about three weeks be zealously guarded against undue exposure to changes of temperature, in order that the cutaneous functions may be conserved; but beyond this their directions concerning prophylaxis are generally vague and indefinite. Now, while most of the cases of scarlatinal nephritis which the writer has seen have seemed to owe their development to exposures, which acted as exciting causes, he has met with other cases in which all possibility of undue exposure was eliminated, in which the bowels were active,

and in which the kidney disease apparently owed its origin to the inherent exciting effects of the scarlatinal poison.

This cause of nephritis must underlie every case and must exert a predisposing influence to renal trouble, the strength of which is in direct proportion to the virulence and to the quantity of the scarlatinous poison acting upon the epithelium of the renal tufts and tubules, as well as upon the pharyngeal, gastric, and intestinal mucous membranes. Since the violence of this toxic action upon the renal tissues can not always be estimated by the severity of the constitutional or of the local symptoms of the fever, it is certainly a wise precaution to endeavor in each case to lighten the burden of the kidneys and to mitigate the poisonous effects of the scarlatinal materies morbi. That the former indication may be properly fulfilled by so sustaining and stimulating the functions of the skin as to render this organ's full emunctory powers available by so regulating the diet that comparatively few irritating excretory products shall pass through the renal epithelial cells, and by calling into action the eliminating power of the intestinal mucous membrane, is self-evident.

In proportion, however, as the perspiration is increased and the intestinal emunctory functions augmented, the urinary secretion is lessened, from which it follows that the most rational method of combating the ever-present predisposing cause of scarlatinal nephritis and of guarding, so far as possible, against its attacks, consists in augmenting the watery constituents of the urine at the same time that the cutaneous and intestinal secretions are held at their normal quantitative standard.

The neglect of this latter precaution has seemed to the writer the weak point of the contemporaneous treatment of scarlet fever. While appropriate measures looking toward the prevention of acute nephritis by dilution of the urine may be strictly enforced during the febrile period, they are too apt to be neglected so soon as the fever has subsided and the appetite has begun to crave solid fosds.

Yet this is the very time when the eliminating function of the kidneys should be kept most active and when the stimulating character of the urine should be reduced to a minimum, as is proved by the frequent inception of renal inflammation during the desquamative period of scarlatina. This view of the subject having forcibly presented itself to the writer's mind, he cast about for the easiest method of simultaneously fulfilling all the indications above stated.

The current methods of encouraging the normal action of the skin by sustaining an even and moderately clevated temperature in the patient's apartments and by daily lukewarm baths, followed by emollient inunctions, seemed perfectly adequate to the efficient accomplishment of their purpose.

The daily evacuation of the bowels by means of unirritating laxatives assured the maintenance of the important eliminative functions of the intestinal mucous membrane at a normal standard. The chief therapeutic problem which presented itself was therefore the selection of the best methods for fulfilling the third essential indication—viz., the dilution and the mitigation of the renal secretion.

A helpful suggestion, found in several books and pam-

<sup>\*</sup> Read before the New York Clinical Society, November 24, 1893.

phlets which came within the writer's reach, consisted in the recommendation that the milk diet be used, both during and after the febrile stage of scarlatina, with a view to the dilution of the urine and to the consequent prevention of nephritis.

Adopting this suggestion, the writer indeed found that the milk diet vielded excellent results, and that under this system the percentage of cases complicated or followed by nephritis at once fell to a very low figure. His experience at that time and subsequently has convinced him that faithful adherence to a strict milk diet, together with a careful observation of the other prophylactic precautions already mentioned, for a month after the cessation of the fever, prevents the development of nephritis in a large majority of the cases, and is, on the whole, the simplest and best prophylactic treatment of this disease. He soon, however, encountered an obstacle to the invariable employment of this treatment in the irreconcilable repugnance to milk manifested by some patients and by the inability on the part of others to adopt an exclusive milk diet, owing to the supervention of more or less distressing digestive disturbances.

Moreover, it was found that so soon as the patients began to move about their rooms and to engage even in such games and pastimes as were adapted to their enfeebled condition, their nutrition was sometimes hardly maintained at a normal point by milk alone, as was attested by a gradual diminution in their weight and by the persistence of their anemia.

Some modification of this method being therefore frequently desirable, the writer instituted some experiments the object of which was to discover the best dietetic and diuretic treatment for the post-febrile stages of scarlet fever compatible with the comfort of the patients and with the maintenance of their strength.

In reviewing the cases which he has treated since that time, the writer finds that they may be arranged in three categories—viz., (1) those in which an exclusive milk diet has been well tolerated for a full month; (2) those in which a mixed diet, consisting of milk and of solid foods, was employed; and (3) those in which milk was not tolerated in any quantities, and the diet was therefore necessarily composed chiefly of solid foods. In all these classes of cases the eliminating functions of the skin and of the bowels were kept active by the means already favorably mentioned.

To patients of the first class a strict milk diet was administered for a month after the cessation of the fever, from one to two quarts of milk being daily exhibited, according to the patient's age and appetite. At the end of that time the modified milk diet belonging to the second class was adopted for two weeks, after which the solid diet was allowed. Even in these cases a careful watch was kept on the urine for two weeks longer before the cases were entirely released from professional surveillance.

At the beginning of the fever peptonized milk was employed whenever the irritability of the stomach demanded it, and sweet milk was at times replaced by junket, whey, skimmed milk, buttermilk, or koumiss. In the event of the appearance of albuminuria after the adoption of the

mixed diet or of solid foods, the milk was forthwith resumed and continued until two weeks after the disappearance of the albuminuria. After that time the mixed diet was used for two more weeks, and finally the solids were again allowed.

The second class of patients embraces those who could only comfortably bear a limited quantity of milk. These patients have generally received two solid meals and two or three milk meals daily, the former consisting of clear and not too salty soups, green vegetables, bread and butter, cream, eggs, fish, oysters, chicken, and later a little fresh beef or mutton, roasted, broiled, or boiled.

Strict injunctions were given that with each of these meals a liberal amount of beverage be allowed—such as hot water with a little milk, very weak tea, or slightly sweetened cocoa. The two solid meals were given at about 8 and 1 A. M., respectively, and the milk meals at about 5 and 9 P. M., and at 2 A. M. in cases requiring nocturnal alimentation.

The third class of patients-viz., those who were unable to tolerate milk in any form without suffering from digestive derangements or losing weight-received the solid foods already enumerated, particular stress being always laid upon a liberal allowance of warm drinks being taken at each meal. In addition to this, a mild diuretic or alkaline remedy was exhibited, with two thirds of a glassful of water after each meal and at bedtime for a month after the cessation of fever. In most instances it seemed advisable to vary the diuretic or alkaline salt employed from time to time, in order to prevent exciting repugnance or gastric irritation by the too protracted use of any one remedy. The writer has employed citrate, bitartrate, bicarbonate, and acetate of potassium, citrate and carbonate of lithium, and bicarbonate of sodium, in doses varying from five to fifteen grains, in accordance with the age of the patient and the quantity of urine secreted. Since the adoption of this plan of treatment the writer has seen about sixty cases of scarlet fever, and of these, only five cases have been followed by nephritis, which was in each instance slight and transitory.

These results, the credit for which is probably largely due to the therapeutic measures employed, have been so satisfactory to the writer that he has ventured to describe them at length before the society, hoping that those members who will do him the honor of participating in the discussion will furnish data, based upon their own experience, facilitating the elimination of any faults of his method, or justifying the substitution for it of some better plan for the prevention of scarlatinal nephritis.

#### A CASE OF

### SPONTANEOUS PODALIC EVOLUTION.

By JULIUS ULLMAN, M. D.,

ROCHESTER, N. Y., HOUSE PHYSICIAN, CITY HOSPITAL

In a recent number of the *Medical Record* (vol. xliv, No. 17, p. 517) Dr. J. McGillicuddy referred to spontaneous evolution, and as this termination of a seemingly difficult labor is both rare and often fortunate, I would report a case

which occurred at the Rochester City Hospital during the service of Dr. W. S. Ely:

Mrs. E. S., aged thirty-four years; occupation, washerwoman; born in Ireland; multipara. Had four normal labors, two abortions; last child two years old. Patient was treated at the outpatient department July 5, 1893, for syphilis. At this time was about five months pregnant. Was again examined September 27, 1893, and no feetal movements or heart sounds could be heard. She was advised to enter hospital at this time. Entered hospital October 22, 1893, at noon. Patient said she was eight months pregnant. Examination revealed no foetal heart sound or movements, and a transverse presentation. Membranes ruptured at 3 p. M. At 8 p. M. pains became very strong; the right shoulder presented and became fixed under the symphysis pubis, and its corresponding hand and arm protruded from the vulva.

It was determined to perform podalic version, and the usual preparations were made. Before, however, they were completed spontaneous podalic evolution took place and delivery was effected by the mother's unaided efforts. The breech and right arm presented and the thorax and head followed. The placenta was expelled simultaneously. The fœtus was dead, partially macerated, and mobile. The placenta was somewhat small and degenerated; the amniotic membranes were not intact, necessitating the introduction of the hand into the uterus for removing portions of the secundines. An intra-uterine douche was given. The woman made a complete recovery. The highest range of temperature during the puerperium was  $100^{\circ}2^{\circ}$  F.

### A CHERRY STONE IN THE NOSE.

RHINOLITH; REMOVAL.

BY GEORGE F. KEIPER, M.D.,

LAFAYETTE, IND.,

EYE AND EAR SURGEON TO ST. ELIZABETH HOSPITAL.

Mr. C. W. G., of Oxford, Ind., came to me on account of deafness and profuse purulent discharge from both ears. His constitution is frail. He is thirty-five years old. For fifteen years he has had catarrh in very marked form, and it has caused him much trouble financially and physically without securing relief. He said that no one had ever looked into his nose, but every one had doctored it empirically. Examining the nares, marked hypertrophic rhinitis was found. In the left nostril the probe clicked upon a hard substance posteriorly situated. I attempted its removal. Was unsuccessful then because my patient fainted. However, on October 12, 1893, its removal was again attempted-successfully then. It was impossible to dislodge it with a probe. I then introduced a heavy nasal duckbill forceps and crushed it and brought some fragments out anteriorly. The remainder was so large as to be impossible to remove anteriorly, and so it was shoved into the pharynx and coughed out through the mouth. Cocaine was, of course, applied during the procedure. It proved a rhinolith, being three quarters of an inch long in longest portion, half an inch wide in widest part, and nearly half an inch thick in the thickest portion. We scraped it and came across a very hard substance. We then broke it and found in its center a cherry stone. The surrounding material was calcareous. It is needless to add that his so-called catarrh is better, and that his middle-ear trouble is disappearing under proper treatment. I doubt not but that his middle-ear trouble was caused by the irritation which such a large foreign body would necessarily produce. He has no recollection of having put a cherry stone in his nose, but thinks he did when a very small boy as a boyish prank.

THE

## NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 6, 1894.

THE FINANCES OF THE ACADEMY OF MEDICINE.

For the first time in many years, the report of the treasurer of the Academy of Medicine has been printed and sent to each of the fellows, who are the stockholders of the organization. This publication, we understand, was not accomplished without the vigorous opposition of some of the trustees, who are said to have taken the remarkable position that the fellows of the Academy should continue in ignorance regarding its financial status. Many of the fellows have desired a more detailed statement, but nobody has seemed willing to take the initiative toward requiring the trustees to print it. In fact, we have heard it stated that some of these officers seemed to think that the Academy was to submit to their dictation rather than they execute the will of the Academy. But the president, Dr. Roosa, urged that the fellows be made acquainted with the value of their property as well as with some of its needs, and a majority of the trustees have concurred in this sensible position and have published this report,

From it we learn that the receipts from all sources during the year 1893 were over sixteen thousand dollars, and the expenditures fifteen thousand dollars, of which almost four thousand dollars was spent for books, journals, binding, etc. It is to be regretted that the receipts are not greater, as it would then be possible to reduce the annual dues, that are now too high and prohibit a great many of the younger men from joining the Academy.

The income from the various library funds is less than nine hundred dollars, while the money now expended for books, etc., though four times that amount, is still insufficient to supply the wants of the library. It is to be hoped that some prosperous members of the profession or some wealthy laymen may appreciate the opportunities for good that further endowments would afford, and, if the matter is properly presented, we may expect further gifts to this valuable feature of the Academy. But, en passant, it would be possible to present a better argument for making such gifts if the recent rule of the library committee to close the library to all but fellows of the Academy after six o'clock were speedily revoked. Let the library do the most good to the greatest number; it was established as a public medical library, and it was largely on the strength of that function that some large gifts to the Academy were secured.

The statement of the building fund is even more encouraging. Through the generosity of certain fellows, as well as through the economical administration of the trustees, there are now but ten thousand dollars in bonds outstanding. The report is a credit to the Academy and will undoubtedly increase the interest of the profession in this excellent organization.

# THE NEW YORK AND BROOKLYN DEATH-RATES FOR 1893.

THE report of the Bureau of Vital Statistics of the Health Department of the City of New York shows that the total mortality in 1893 was 44,370, so that the death-rate was 23.4 in a 1,000. This is the lowest rate since 1877. In 1892 the deaths numbered 44,329 and the rate was 24.26 in a 1,000. The births reported in 1893 were 51,516 in number, and the marriages 16,144. The deaths of children under a year old numbered 11,105, those of children under five 17,872, and those of persons sixty-five years old or older 4,430; 10,600 deaths occurred in institutions. Among the principal causes of death, pneumonia appears to have been the most destructive. It caused 6,476 deaths, while pulmonary consumption caused only 5,101. Heart diseases occasioned 2,376 deaths, and the various forms of Bright's disease gave rise to 2,561. Cerebro-spinal meningitis is charged with an extraordinary total-467 deaths, a number almost equal to that attributed to croup, 587. Bronchitis caused only 1,569 deaths. There were 1,565 accidental deaths and 313 suicides. The following numbers of cases of various infectious diseases were reported: Diphtheria, 6,224; measles, 6,831; scarlet fever, 5,637; small-pox, 449; typhoid fever, 1,010; and typhus fever, 470. The mortality from these causes is to be published hereafter.

The usual Mayor's report in Brooklyn, regarding the year just closed, shows a death-roll of 21,380, with a part of the December mortality estimated, which is commensurate with a death-rate of 21.6 per mille. The population of the city was estimated at the middle of the year at about 988,200. The deaths and death-rate in 1892 were respectively 20,807 and 21.62 in a 1,000. The city was spared the visitation of cholera or any other severe pestilence. Small-pox reared its head from time to time, but was not allowed to assert itself long, A corps of vaccinating physicians, thirty in number, reported the performance of 11,000 vaccinations and 40,000 premises visited to offer protection against small-pox. The measures against cholera included the enlistment of the pacteriologicalservices of Dr. George M. Sternberg, who has recently become the surgeon general of the army. The Brooklyn water supply was the point first investigated by General Sternberg. Under his supervision an analysis was made weekly, and a fair knowledge gained of the existing conditions. The mayor allowed a special anti-cholera expenditure of \$7,500. The total expense account of the department having charge of the city's health was \$190,000 of which \$130,000 went for salaries. Among the other expenses were \$15,000 for ambulances and \$30,000 for the Contagious Diseases' Hospital. The reported number of births was, as usual, below that of deaths-namely, 19,300 births. The number of marriages was 7,350.

### MINOR PARAGRAPHS.

MEDICAL MISSIONARIES IN AFRICA.

CAPTAIN LUGARD'S recent book \* is replete with references to the Scottish and other medical missionaries he has met in eastern Africa. The captain offers his testimony in a nonpartisan way, since he does not admire all members of the missionary profession, but he freely admits that "he did not meet one Scotch missionary in Nyassaland whom he did not esteem. He has nothing," says a contemporary, "but praise for them and their methods. He considers that a missionary must, above all things, be a gentleman, 'for no one is more quick to realize a real gentleman than the African savage.' The captain evidently means both the spirit and manner of living of the missionary, and, of course, not anything in a merely conventional sense, as he adds that the dwelling-house of the missionary should be as superior to those of the natives as he himself is superior to them." The following citation from his book is the clearest statement made by an outsider that we have read touching the scope of medicine in the mission field. Captain Lugard says: "Beyond doubt, I think, the most useful missions are the medical and the industrial, in the initial stages of savage development. A combination of the two is, in my opinion, an ideal mission. Such is the work of the Scotch Free Church on Lake Nyassa. The medical missionary begins work with every advantage. Throughout Africa the ideas of the cure of the body and of the soul are closely allied. . . . As the skill of the European in medicine asserts its superiority over the crude methods of the medicine man, so does he in proportion gain an influence in his teaching of the great truths of Christianity. He teaches the savages where knowledge and art cease, how far natural remedies produce their effects, independent of charms or supernatural agencies, and where divine power overrules all human efforts. Such demonstration from a medicine man, whose skill they can not fail to recognize as superior to their own, has naturally more weight than any mere preaching. A mere preacher is discounted and his zeal is not understood. The medical missionary, moreover, gains an admission to the houses and homes of the natives by virtue of his art, which would not so readily be accorded to another. He becomes their adviser and referee, and his counsels are substituted for the magic and witchcraft which retard development."

# LINEAR ATROPHY OF THE SKIN AFTER TYPHOID FEVER.

The British Journal of Dermatology for December, 1893, contains the report of a case of typhoid fever in which linese atrophics appeared as a sequela. The patient came under the notice of Sir Dyce Duckworth, M. D., three months after recovering from a sharp attack of the fever, complaining of extraordinary sensitiveness of various stripes on the outer side of the thighs and on the legs above the malleoli. Examination of the parts revealed several longitudinal stripes of linear atrophy over the legs, with no other evidence of nerve disease. The occurrence of such a condition, together with the hyperæsthesia, pointed, the author thought, to the neurotrophic nature of the lesion, and indicated that both trophic and sensory branches of nerves might thus give token of the damage wrought upon them by the special toxine of typhoid fever.

<sup>\*</sup> The Rise of our East African Empire: Early Efforts in Nyassaland and Uganda. By Captain F. D. Lugard, D. S. O., etc. Two volumes. Blackwood, 1893.

#### TEUCRIN IN LOCAL TUBERCULOSIS.

The December number of Les Nouveaux remèdes refers again to the efficiency of teucrin as a remedy in the treatment of local tubercular affections. Mosetig-Moorhot, according to the Wiener medicinische Presse, has been giving the drug a fair trial and is highly satisfied with the results. The medicament is used subcutaneously at the base of the degenerated tissue, and cures by causing sloughing of the tubercular parts. Great judgment must be exercised, it is said, both as to the quantity of the drug used and as to the number of applications; one is to be guided entirely by the slowness or rapidity of its action. The author has never seen any systemic reaction to the drug exhibited, and thinks that, employed with care, it is a very safe and sure remedy for the extirpation of local tuberculous disease.

#### THE TEACHING OF COMPARATIVE ANATOMY IN CHICAGO.

The showing that Professor Ohlmacher is able to make, in his article published in this issue of the Journal, of the work accomplished by the students of the Chicago College of Physicians and Surgeons in elementary comparative anatomy and embryology seems to us most creditable. Such teaching must tend powerfully to raise up a generation of physicians and surgeons of far greater breadth and depth of education than can now be said to characterize the majority of our profession in the United States. It is graceful, too, on Professor Ohlmacher's part to put his pupils' achievements on record.

#### THE CONGREVE "REMEDY" FOR CONSUMPTION

This name brings to mind those quackish "God-provided remedies advertisements of which are almost constantly to be seen in the religious newspapers of Great Britain. Within the past year, we understand, a Congreve branch has been started in the United States, and fulsomely flattering advertisements have begun to crop out in our own religious journals. A published analysis tends to show that the Congreve medicines consist of an infusion of elderberries with Friar's balsam.

#### THE TOXICITY OF VIPER'S BLOOD.

THE Lancet's Paris correspondent says that M. Phisalix and M. Bertrand have shown by experiments on guinea-pigs that the poisonous properties of viper's blood are considerable, and that the symptoms induced are of the same nature as those provoked by the same snake's venom.

#### ITEMS, ETC.

The Lunatic Asylums of New York State and the Commission in Lunacy.—In their fifty-first annual report to the Legislature, for the year ending September 30, 1893, just published, the managers of the Utica State Hospital say:

"Some friction having arisen between the Lunacy Commission and this board, as well as between the commission and other boards of managers, we are perhaps called on to correct some misrepresentations and submit to your honorable body our views on this important question. This board is not, as has been stated, opposed to State care, either in theory or practice. It favors State care wisely and honestly administered. This board has declined and still declines to sit in silence under wholesale accusations of mismanagement, not to say downright dishonesty, made in public prints at the instance of the Lunacy Commission. We felt it due our self-respect in a formal way to deny these groundless charges, and did so as publicly as they were made. Under the statutes as now construed, there is opportunity to place great responsibility upon managers should anything

go wrong, but they are deprived of any authority whereby they can embody their convictions of what is best in any form more substantial than opinions and their verbal expressions. They can not order the purchase of even so much as a barrel of flour without the commission's consent, and, if refused, the flour can not be provided that month, though it stand between the patients and no bread. Were this the proper time and place, numerous instances illustrating this state of affairs could be given, showing how great hardship may be suffered by the hospitals as the result of arbitrary construction put upon this law in its practical enforcement.

"We do not wish to be understood as opposed to supervision. On the contrary, we approve of it and invite it. We do object to interference which is detrimental to the service and injurious to the patients who are the most unfortunate of the State's wards. Insane people are sick people and should be treated as such. There is no law and we hope there never will be a law which enables any taskmaster here or in Albany to drive these men and women out to work at hazardous or dangerous employment. We believe in proper occupation under competent supervision, as a remedial agent, and regard it as an important part of treatment. We hold, however, that it is an incident on the road to recovery and not the chief business of patients. We furthermore respectfully submit that there is a wide discrepancy between actual and alleged savings under the present system as enforced since October 1, 1893.

"If it be thought by your honorable body wise and best to put the entire control and management of the nearly nine thousand insane in the hospitals of this State into the hands of three men; if it is counted advisable to centralize the authority with the immense power which in this case accompanies it; if it is deemed desirable to make the several institutions part of one monstrous machine absolutely manipulated and governed from the capitol of the State, then present tendencies should be encouraged. In such a view of it there is no longer any need for boards of managers, and the theory of home rule is abrogated and the pretense of it need be no longer maintained. We believe the managers chosen by the Governor and confirmed by the Senate are men of character and ability, who can be trusted to honestly conduct the State's greatest charity. That it should be done under some competent and broad-minded supervision we affirm, but that it should be arbitrary to the last penny we not only question, but emphatically deny.

"We respectfully submit that managers who weekly and often twice or three times a week visit the hospital are better informed of its actual needs than any central authority can be which of necessity is able to make personal inspection only a few times each year. In such large institutions there often arise emergencies demanding prompt attention and instant expenditure. The delay in sending to a busy commission a hundred or more miles away, whose members at that time may be on a tour of inspection anywhere in the State, is often the loss of valuable time liable to prove dangerous and disastrous. Furthermore, it is frequently very difficult by telephone, telegraph, or letter to make plain a series of circumstances or a state of affairs which would be apparent at a glance to a person on the ground and in possession of all the facts. If local boards of managers are to exist at all and be useful, they should bave larger powers and more latitude than is allowed them by the present narrow construction put upon the statute. We resent as unfounded and undignified the insinuation of the commission that power is asked by the managers only for the pleasure its exercise may afford. They serve without salary, nor have they been guilty of any attempt to glorify themselves either for real or imaginary accomplishments. They give their time and strength as a part of a citizen's obligation, feeling that the best evidence of appreciation for an honorable appointment is the conscientious discharge of the duty it imposes. The accusations of the commission to the contrary not withstanding, the history of this present board of managers ought to be of itself a refutation of any charge, and if it is not, the books are open for your inspection and the most careful scrutiny is invited. So long as we are intrusted by the State with a duty, the obligation to discharge it to the best of our ability can not go unheeded. We should certainly most cordially co-operate with any supervisory State authority, whose interest is the furtherance of the best service in the most economical way, and no account taken of personal preferment or ambition. Our attitude is not one of hostility toward any person or persons as such, but is rather the expression of our recognition of the duties and responsibilities which rest upon us in the conduct of a great charity. Responsibility without power is useless and, as we believe, unfair and unjust.

"We beg to suggest that at its present session your honorable body give attention to this phase of the subject, with a view to harmonizing existing difficulties and differences, that the insane may be most intelligently cared for, that the service may be improved, and the administration made at once wise and economical."

We think the managers are warranted in their contention, and it is gratifying to observe that that portion of the Governor's message that refers to the matter is more favorable to them than might have been expected from the newspaper reports of recent conferences on the subject in which the Governor took part.

The New York Academy of Medicine.—The programme for the meeting of Thursday evening, the 4th inst., included a paper entitled Observations upon Abdominal Surgery in Relation to the General Practitioner, by Dr. A. Vander Veer, of Albany.

At the next meeting of the Section in General Surgery, on Monday evening, the 8th inst., Dr. James P. Tuttle will read a paper on The Modern Treatment of Hæmorrboids, Dr. C. A. Powers will read one entitled Further Observations on the Physiological Occurrence of Conical Stump after Amputations in Children, and Dr. Willy Meyer will present a portable sterilizer for private operations.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 9th inst., Dr. C. W. Allen will read a paper on Gangrene of the Scrotum.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 11th inst., the subject of skin diseases in children will be discussed by Dr. L. Duncan Bulkley, Dr. J. P. McGowan, and Dr. George H. Fox; and Dr. Henry Koplik will read a paper on Anal Fissure and Painful Erosions of this Region in Infants and Children.

At the next meeting of the Section in Neurology, on Friday evening, the 12th inst., Dr. Charles H. Knight will read a paper on Reflex Disturbances allied to Lesions of the Rhino-pharynx, and Dr. Lightner Witmer will read one on Pain from the Point of View of the Psychologists.

The Shelby County, Indiana, Medical Society.—At the next meeting, on Monday afternoon, the 8th inst., Dr. I. W. Inlow will read a paper on Alcohol.

Changes of Address.—Dr. W. H. Bates, to No. 173 Remsen Street, Brooklyn; Dr. R. Harvey Reed, from Mansfield; O., to No. 150 East Broad Street, Columbus, O.

The Death of Dr. Francis Minot Weld, of Jamaica Plain, Mass., occurred on December 31st. Dr. Weld was born in 1840 at Dalton, N. H., and was graduated in arts and medicine

from Harvard University. During the late war he served as a medical officer in the navy and afterward in the army. In 1866 he settled in New York, and for a time held the medical superintendency of the New York Hospital. He was one of the founders of the University and Harvard Clubs, and had been president of the latter.

The Death of Dr. Robert C. McEwen, of Saratoga Springs, N. Y., occurred at his residence on the evening of December 26th, in the sixty-first year of his age, from intercurrent pneumonia following cerebral embolism.

He was a graduate of Williams College, of the class of 1853. His first course in medicine was at Yale, and he studied in the office of Dr. N. B. Ives, of New Haven. He then entered the office of the late Professor J. M. Smith, of New York, and was matriculated at the College of Physicians and Surgeons. He was graduated from that school in 1856 and became at once attached to the house staff of Bellevue Hospital. After the close of his term in the hospital he went abroad, and upon his return, in 1860, began practice in Stratford, Conn. When the war broke out he entered the field as assistant surgeon of a Connecticut regiment and remained in the service until September, 1863, when he resigned on account of sickness and soon afterward began practice in New York. At the end of three years he moved to Saratoga, where he continued in active work up to within a few weeks of his death, and was honored by everybody in the community in which he had lived so long.

The Death of Dr. Horace Hollister, of Scranton, Pa., removes one of the pioneers of the Lackawanna region. He was a graduate of the Medical Department of the University of the City of New York, of the class of 1846. He was an authority in local archæology, the historiographer of the Lackawanna valley, and a collector of aboriginal relies and of Americana, His collections are among the finest in the country. His death occurred on December 29, 1893, in the seventy-first year o his age.

The late Sir Andrew Clark's Estate.—According to the British Medical Journal, the net personal estate in the United Kingdom left by the late Sir Andrew Clark, M. D., amounts to £203,969. Among his bequests was one of £500 to the London Hospital Medical College for the foundation of a scholarship.

#### Society Meetings for the Coming Week:

Monday, January 8th: New York Academy of Medicine (Section in General Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society (private); Boston Society for Medical Improvement (annual); Gynæcological Society of Boston; Baltimore Medical Association; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Shelby County, Ind., Medical Society.

Tuesday, January 9th: New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private, election); Kings County, N.Y., Medical Association; Medical Societies of the Counties of Chautauqua (semi-annual), Chenango (annual), Clinton (annual—Plattsburg), Erie (annual—Buffalo), Genesee (semi-annual—Batavia), Greene (quarterly), Jefferson (annual—Watertown), Livingston (semi-annual), Madison (semi-annual), Oneida (semi-annual)—Rome), Onondaga (semi-annual—Syracuse), Ontario (quarterly), Oswego (semi-annual—Oswego), St. Lawrence (annual), Schenectady (annual—Schenectady), Schuyler (annual), Steuben (semi-annual), Tioga (annual—Owego).

Wayne (semi-annual), and Yates (semi-annual), N. Y.; Norfolk, Mass., District Medical Society (Hyde Park); Newark, N. J., Medical Association (election); Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Trenton, N. J., Medical Association (private); Northwestern Medical Society of Philadelphia; Baltimore Gyamecological and Obstetrical Society; Practitioners' Club, Richmond, Ky.

Wednesday, January 10th: American Microscopical Society of the City of New York; Metropolitan Medical Society (private); New York Pathological Society (annual); New York Surgical Society; Medical Societies of the Counties of Albany and Dutchess (annual—Poughkeepsie), N. Y.; Tri-States Medical Association (Port Jervis, N. Y.); Pittsfield, Mass., Medical Association (private); Hampshire (quarterly—Northampton) and Worcester (Worcester), Mass., District Medical Societies; Bennington, Vt., and Hoosick, N. Y., County Medical Society (annual—Arlington, Vt.); Philadelphia County Medical Society; Kansas City, Mo., Ophthalmological and Otological Society.

Thursday, January 11th: New York Academy of Medicine (Section in Pædiatrics); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society (annual and election); Medical Societes of the Counties of Caynga, Fulton (annual—Johnstown), and Rensselaer (annual), N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, January 12th: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties.

Saturday, January 13th: Obstetrical Society of Boston (private); Worcester, Mass., North District Medical Society.

# Proceedings of Societies.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting of December 4, 1893.

The President, Dr. WILLIAM HUNT, in the Chair.

'Remarks upon the Treatment of Stricture of the Sigmoid Flexure and of the First Portion of the Rectum.— Dr. John B. Deaver read the following paper:

My object in offering a few remarks upon stricture of the sigmoid flexure and of the first portion of the rectum this evening is to obtain the views of the fellows present upon this, which is certainly a very important, subject, and to place upon record a case of stricture of the terminal portion of the sigmoid flexure and of the first portion of the rectum, recently under my care, in which the passage of a flexible rubber bougie (Wales) but one size, French scale, larger than that which had been passed many times before, caused perforation of the rectum below the stricture, resulting in the death of the patient within twenty-four hours thereafter from peritonitis. In order to discuss this subject to the best advantage I may be permitted to refer to one or two points in the aniatomy of the first portion of the rectum, also to say a word or two concerning the diagnosis of stricture situated beyond the reach of the finger.

The rectum does not, as is usually described, begin at the brim of the pelvis opposite the sacro-iliac synchondrosis, whence it extends to about the center of the third piece of the sacrum and descends in front of the sacrum, the coccyx, etc., but com-

mences at the terminal part of the omega loop, to which attention has been called by Treves as being the shape of the sigmoid flexure, and not S-shaped in answer to the description in the text-books on anatomy. Careful examination by myself of many bodies has confirmed the above statement. All of the omega loop, which includes the first portion of the rectum, occupies the pelvis in the adult. It will thus be understood that the first portion of the rectum makes with the second portion a decided angle; therefore an instrument of the caliber of the normal bowel, unless it be a flexible one which will pass through the third and the second portions, will not prove anything regarding the caliber of the first portion. Again, from the relation borne between the second and the first portions of the rectum much may be learned about the latter if it be infiltrated, upon introducing the finger into the second portion, through the walls of which the infiltration may be detected. The best form of flexible rubber bougie is one which is hollow, as the Wales instrument is, to the lower end of which can be attached a fountain or Davidson syringe, and water thrown through this, favoring its passage by drawing out of the way the folds of the mucous membrane which would otherwise form an obstruction to its introduction.

The diagnosis of stricture of the second and third portions of the rectum is readily made by the sense of touch. When the index finger is not long enough to reach beyond the second portion with the patient lying on the back, it may be done with ease if the patient be turned upon the left side and the thighs slightly flexed upon the abdomen and the finger introduced into the anus from behind, as the tissues of the perinæum can be carried a little distance in advance of the web of the index and middle finger. Contraction in this part of the bowel can often be diagnosticated by the introduction of a short, flexible Wales bougie, but the finger is the more trustworthy instrument. This, too, is the only portion of the bowel where we shall all admit that the operation of proctotomy for the relief of a contraction is admissible. The soft, flexible rubber bougie is the only instrument that can be carried safely as well as surely through the upper portion of the rectum and the sigmoid flexure. The non-flexible rectal bougie is not only an unsafe instrument, particularly where the stricture is situated beyond the second portion of the rectum, but one which may mislead the surgeon in making a diagnosis of stricture when it does not

The first portion of the rectum, like the sigmoid flexure, is connected to the back part of the abdominal cavity by a reflection of the peritoneum, the meso-rectum. On account of the bend made by the junction of the first and second portions of the rectum, it can be readily seen how the point of a non-flexible bougie is arrested by contact with the wall of the bowel at this point, which offers resistance to its further passage, and a diagnosis of a pathological obstruction made; or it may be that the bowel, owing to the meso-rectum being preternaturally long, will be carried in advance of the point of the instrument to or beyond the median line in the neighborhood of the pubes, while, if the instrument by chance should pass into the sigmoid flexure, the latter, owing to the meso-sigmoid, may be carried to or beyond the median line in the neighborhood of the umbilicus, which, in either event, might give rise to the belief that the bougie had passed into the bowel beyond, if not through, a supposed stricture.

There is a question of doubt in the minds of some as to the possibility of being able to carry a flexible rubber tube or bougie through and beyond the sigmoid flexure. This has been tried upon the dead body in a number of instances, and, not having proved successful, the deduction has therefore been made that it is impossible to do it in the living subject. While

I am aware of the difficulty attendant upon the introduction of an instrument into the descending colon in the dead body, due chiefly to the absence of muscular contractility, which facilitates the passage of the instrument on the one hand and offers a very decided barrier against its introduction on the other, also to the absence of the normal moisture in the shape of the mucus, I can not admit this to be so.

We well know that it is much easier to introduce a bougie through the normal urethra in the living subject than it is in the cadaver, and yet this ought to be more readily accomplished in the case of the urethra, where counter-pressure can be brought to bear to aid in the introduction of the instrument, than in the case of the bowel. I have very satisfactorily demonstrated upon many occasions the possibility of being able to circuit the sigmoid flexure with a soft, flexible tube such as the long flexible rectal bougie and the long flexible colon tube. In certain cases of intestinal obstruction I regard the passage of a soft, flexible tube into the sigmoid flexure, through which water can be thrown and the capacity of the large bowel ascertained, an important aid in the diagnosis between obstruction of the small and obstruction of the large intestine.

With the subjective symptoms of stricture of the large bowel present-namely, constipation, or may be attacks of diarrhora -the passage of ribbon-shaped stools or of choppy stools covered with mucus and blood, or preceded or followed by the passage of mucus and blood attended by tenesmus, the lower portion of the rectum being intact, as proved by a digital examination, it does not absolutely follow that a stricture is the cause in all instances, as we may see this train of symptoms consequent upon a subacute or chronic catarrhal inflammation of the colon, of the sigmoid alone, or in ulceration of the sigmoid flexure; therefore, before we can get more definitely at the exact condition of affairs it will be necessary to resort to instrumental interference in the introduction of graduated sizes of flexible rubber bougies, when a diagnosis can generally be arrived at with a very fair degree of certainty. This should be done with all due care, and preferably by one experienced in the use of these instruments, as it has been demonstrated, particularly in the case I report to-night, that serious results can accrue from even the passage of a soft instrument, which argues strongly against the use of inflexible or semi-flexible instruments. From the relation the first portion of the rectum holds to the second when the former is the seat of extensive thickening or the walls contain a growth upon digital examination this can usually be detected. In this class of cases, as in disease of the second and third portions if in the female, much can be learned by careful digital examination of the vagina. I have on several occasions been able to feel with the finger masses in the first portion of the rectum, as well as the presence of a growth which had assumed some size in the terminal portion of the sigmoid, by carrying the vault of the vagina well in advance of the examining finger, aided, too, by counterpressure made over the abdominal walls. Further, I believe these examinations are better made without ether, having the feelings of the patient to guide us and with less risk of injuring the bowel.

Where a mass is suspected in connection with symptoms of stricture, which would suggest malignant disease, there is considerable to be gained, however, by giving the patient ether, under the influence of which the abdomen can be palpated more satisfactorily. Another means of diagnosis—that of dilating the sphincter of the anus and the introduction of the hand into the rectum and the sigmoid—I have never had the courage to do. In cases of great doubt, rather than resort to the last procedure, I deem it more advisable to do an exploratory abdominal section. Exploratory abdominal section, however, done for the

purpose of diagnosis in the questionable cases of stricture of the sigmoid and the first portion of the rectum, I am not a strong advocate of, as I think that a diagnosis in the majority of cases should be made without resorting to so complicated a measure. While I am aware of the little risk attending an exploratory abdominal section under strict cleanliness, I think the principal objection to be urged against it is that it lessens the responsibility of the surgeon as a diagnostician. Apart from this, I fear the modern tendency is too much in the direction of exploratory incisions in other regions of the body, as well as the abdominal cavity, for diagnostic purposes.

The operation should be the natural sequence of the diagnosis and not the diagnosis to the operation. Perfecting one's self in diagnostic attainments is certainly more creditable to a surgeon than to feel forced to have to open the belly cavity to determine that which may be done without.

The majority of cases of benign stricture involving the first portion of the rectum are amenable to treatment by either the bougie or colotomy. Stricture of the sigmoid flexure, very rare except when of malignant origin, is not nearly so favorable for gradual dilatation by the bougie. Stricture here located, be it benign or malignant, if the inflammatory process has not advanced too far to permit of resection and anastomosis, or perhaps circular enterorrhaphy, the most that can be hoped for in the majority of instances is the establishment of an artificial anus in the loin.

The choice between iliac and lumbar colotomy must depend upon the merits of each case; ordinarily I prefer to make the operation through the loin. The only advantage I can see in the anterior (iliac) operation is the opportunity it affords to determine definitely the condition of the bowel, if a resection and anastomosis or enterorrhaphy is possible, and, if nothing short of an artificial anus will suffice, the making of it at once.

In a paper I read before the Philadelphia County Medical Society two years ago upon Lumbar versus Iliac Colotomy, I took the ground that the lumbar operation was the more preferable, inasmuch as the diagnosis of the condition rendering the operation of colotomy necessary should, in the majority of the cases, be made without having to open the peritoneal cavity as is done in the iliac operation.

In benign stricture of the sigmoid flexure and of the first portion of the rectum, I recommend gradual dilatation by means of the flexible rubber bougie. When this is not possible, more radical measures must be adopted. In malignant stricture of the above portions of the bowel the bougie can do nothing other than harm; directly, by hastening the diseased process, and indirectly, by misleading the patient in having him believe that an operation will not be required. I believe the earlier radical operative interference in malignant disease of the bowel is instituted the better, and that if this practice was followed in all instances patients' lives would certainly be very materially prolonged and, in some cases, the disease perhaps eradicated by removing it while yet local. What holds good in the uterus and elsewhere regarding affections of this character, holds equally good in case of the bowel, the difficulty in affections of the latter organ being that not exposed to the sense of sight, the diagnosis can not be made with the same degree of certainty as in like conditions of the uterus, the breast, etc.

The advisability of furnishing the patient with a bougle and instructing him to pass it himself I am inclined to question; I think this is better done by the surgeon. In addition to instrumental and operative treatment, much is to be gained by constitutional treatment, particularly if the case be of specific origin; but unless the history clearly points to this we should be careful not to push the treatment too far for fear of the debilitating effects; by attention to the general health, by the administra-

tion of tonics, by advising the proper diet, by giving tonic laxatives to have the bowels moved daily.

In cases where tenesmus is excited by the presence of a collection of mucus it is advisable to introduce a long flexible rubber tube beyond the stricture, through which the bowel can be irrigated with warm water or with mild antiseptic astringents.

The following is the case I have referred to above: F. W. R., aged about thirty years, consulted me July 27th, stating that he had a stricture of the large bowel, for which he was passing at intervals of from four to five days Nos. 9 and 11 Wales bougies by the advice of his physician. Upon being questioned, he described the symptoms characteristic of stricture of the sigmoid flexure, or of the latter and first portion of the rectum. He further stated that without the aid of medicine taken internally or the use of enemas it was impossible for him to have a passage. Digital examination of the rectum revealed nothing other than a rather capacious organ. Examination with the bougie showed the presence of an unquestionable obstruction nine inches within the anus. I advised continuance of the local treatment, but disapproved of his using the bougie himself. I I passed a bougie up to the time of his last visit to me, when, upon introducing one a size larger than the one usually usednamely, No. 12-which I had also passed before with but little difficulty, as the point of the instrument was engaging in the stricture he suddenly lurched forward upon the operating chair, and before I could withdraw the instrument he rebounded, as it were, upon the point of the bougie. This was immediately followed by severe abdominal pain. I feared the bowel had been penetrated on the anal side of the stricture, but was not certain, as the instrument was withdrawn clear of blood, and there was no blood passed after its withdrawal. I advised that he go to the hospital, where he would have the benefit of abso lute rest and at the same time give me the opportunity of having him closely observed. Contrary to my advice, he went to his place of business, but came back to my office some time afterward, complaining of the pain being as severe as when he left me earlier in the morning. He now consented to go to the hospital. The pain was so severe as to require large doses of morphine to relieve him. He would not consent to an abdominal section, therefore I was powerless to do other than administer anodynes, counterirritants, etc. He died during the following night. The abdominal walls remained perfectly rigid, with the absence of tympany until four hours before he died, when there was pronounced distention. An autopsy made shortly after death showed the presence of a purulent peritonitis and a linear stricture involving the terminal portion of the sigmoid flexure and the first portion of the rectum. The bowel immediately below the stricture, which was very much dilated, with the wall nearly as thin as tissue paper, showed a perfora tion. Upon opening the bowel, there were present cicatrices which were evidently the result of ulceration. There were present old adhesions in the abdominal cavity in the neighborhood of the descending colon and sigmoid flexure. Upon opening the chest, there were present adhesions at the apices of the lungs. There was no further evidence of organic disease.

A few hours before his death, in a conversation with his mother, I learned, much to my surprise, that he had for some time back been giving himself an enema after each meal; this, to some extent at least, evidently accounted for the very much dilated and thin condition of the wall of the bowel, rendering it susceptible to penetration by the bougie.

The President said: I have recorded the following case in several places: Years ago I attended a gentleman who, as a result of disease of the cervical medulla, was thoroughly paralyzed. Every day the intestines would fill with flatus, and I would inroduce a tube beyond the sigmoid flexure and allow the gas to

escape. This could be done in this case without the slightest difficulty. I do not know whether or not the relaxation from the paralysis had anything to do with it. I have tried to repeat the procedure since in the living subject, but have not succeeded. I have also read in some French authorities that it is impossible.

Dr. Thomas G. Morton said: I have knowledge of two cases of rectum perforation, neither of which was in my practice. The first case was a female of sixty or more years of age, who had been subject during the greater part of her adult life to constipation, for which enemata and mild laxatives gave relief. For a month or two before her death this condition had become more troublesome, and relief only partial; a digital examination by her physician, who pronounced double stricture with fæcal accumulation and advised bougie dilatation; and shortly afterward made an attempt at digital stretching, which was followed by the introduction of a tube and an enema. An hour later the patient went into shock, and then profound collapse, and died forty-eight hours later. The autopsy showed an organic stricture, and a perforation of the bowel and general peritonitis, the injection having been thrown into the abdominal

The other case was a very similar one; intense pain followed the use of the dilator and injection, and the patient died very shortly, of peritonitis. I have, however, treated very many strictures at the location mentioned by Dr. Deaver, where much relief was afforded by the use of bougies.

Dr. T. S. K. Morton said: The reader of the paper stated that he had found a capacious rectum, and said he believed that possibly the distention and weakening of the rectum were due to the frequent use of enemata. I call to mind an article by Mr. Thomas Bryant, referring to stricture of the rectum, in which he spoke of "ballooning" of the rectum as one of the symptoms. He regarded it as almost diagnostic of stricture. Mr. Bryant offered a number of theoretical explanations for the condition, all of which I do not at the moment recall. One was atrophy, from interference with nutrition; another, the retention of gas. He did not mention the possibility of its resulting from the use of enemata.

Dr. Deaver said: I was especially desirous of reporting this case, as the perforation was made by a soft instrumentmuch more flexible and soft than is used by most surgeons. It is only in recent years that I have been induced to use the soft instrument. I was surprised to have a result of this kind with an instrument which will double on contact with the hands.

I recall the paper of Mr. Bryant to which reference has been made. I have noticed this ballooning of the rectum in many cases, and in some cases of acute mechanical intestinal obstruction from plastic peritonitis, appendicitis, etc. It seems to be associated with obstruction of the bowel, and perhaps in my case it was a consequence of the stricture; but I think it is bad practice to use enemata at the rate of three a day, for fear of bringing about an atrophic condition of the bowel. In my paper I advise against the use of instruments in the rectum, as the finger is the best instrument; but beyond the second portion of the rectum we are not able to discover a stricture with the finger, and we must use a bougie. These are difficult cases to diagnosticate, and there is always an element of risk in the use of a bougie.

Tetanus. - Dr. WILLIAM G. PORTER reported the following: Helmer E., aged twenty-three years; nativity, Sweden; occupation, machinist; weight, two hundred and fourteen pounds; height, six feet two inches. Patient presented an excess of adipose tissue; skin and mucous membranes pale; had had pneumonia in 1892; was addicted to the use of alcohol, especially beer.

He was brought to the Philadelphia Hospital on the fourth

day of the disease, at 1 A. M., November 11, 1893, with the history of having run a rusty nail in the sole of his foot, two weeks previously, while working in a cellar.

The wound gave no trouble, healing in a few days. Ten days after the injury he noticed some pain upon swallowing. The next morning his jaws were stiff, by evening he could not open his mouth, his back was stiff and the seat of severe pain, which he described as feeling like a band of constriction, passing from the back around the abdomen and down into the legs. Upon admission the jaws were firmly locked, the masseters hard, risus sardonicus present. There was a moderate degree of continuous opisthotonus, the abdominal muscles were boardlike, and when lifted from the stretcher to the bed he moved as if made of one rigid piece, there being no motion in any joint from his head to his feet. Paroxysmal spasms occurred every one to three minutes, increasing the contractions of all the muscles involved in tonic spasm.

His pulse was soft and rapid, heart sounds weak, temperature 99° F., bowels had not moved for three days. An evacuation was secured by means of croton oil and a laxative enema. A little ether was given and a free and deep incision made where the punctured wound had been; it was thoroughly cleansed with bichloride (1 to 200), and a wet bichloride dressing applied. He was placed upon the combined bromides, forty-five grains, with chloral, fifteen grains, every three hours. Nitroglycerin, one drop, every fifteen minutes till three doses were given, then every hour till there was flushing of the face, then every two hours.

Uranalysis showed a high-colored urine, specific gravity 1.033, a decided ring of albumin, an excess of chlorides, and a few granular casts.

The full effect of the chloral was not secured till the third day after admission, when there was given by the bowel during the afternoon two drachms of chloral with five drachms of bromides. He now slept soundly, and during the sleep there was less arching of the back and some relaxation of masseters. The paroxysmal spasms, however, did not seem to be influenced by the chloral. Its use by the bowel was continued, giving it in such doses and at such intervals as seemed indicated.

A free perspiration marked the entire course of the disease. Within a few hours after admission the temperature became normal, and remained so till the seventh day, when it began a slow but continuous ascent.

Feeding was not difficult; the nozzle of the feeding cup was placed between his lips and the contents found their own way to his throat, frequently, however, causing repeated spasms of the pharyngeal muscles. For the first few days he was eager for milk, and five pints were given daily; later he did not care for nourishment, but continually craved beer. Eggs were given in milk and with sherry wine.

Dur ng the seventh day of the disease there was much less pain in the back. There was considerably less spasm; patient expressed himself as feeling much better. His mind had been perfectly clear up to this time, but during the night there was a little delirium, and a slight tendency to pick at the bed clothes.

Eighth day.—Lower jaw drops a little during sleep, head not thrown back, paroxysms frequent but not severe. During the night considerable delirium and some twitching of the muscles and carphologia.

Ninth day.—All continuous spasm had disappeared, mouth open, and a guard was placed between the teeth to protect the tongue being bitten during the paroxysms, which were marked by prompt snapping of the jaws. At 5.30 r.m. he had a prolonged and severe spasm, after which there was a great muscular relaxation; urine and fæces were passed involuntarily, res-

pirations became very shallow, no radial pulse could be felt, and he became profoundly unconscious.

At noon his temperature had been 104°; at 5.30 it was 106°; at 6, 107°; at 6.30, 108°; at 7, 109°. At 7.20 the heart ceased beating. Shortly after the cessation of respiration, half an hour later, the temperature of the body was 111°. Antitoxine: Upon the evening of the seventh day the administration of antitoxine was begun. It was deeply injected into the muscles of the thigh twice daily in ascending doses. The first dose was 20 centigrammes, the last dose 160 centigrammes.

This treatment appeared to have no influence upon the symptoms. There were no local effects at the points of injection. The temperature had begun to rise before the first dose was given.

A post-mortem examination was not secured by the hospital authorities, but was, however, secured after the removal of the body. The membranes of the brain and cord were found intensely hyperæmic; the brain was ædematous; the ventricles and central canal of the cord were distended with fluid. The brain and cord are preserved for further examination.

Heart flabby and relaxed. The blood in the auricles and great vessels was dark and fluid. Nothing noteworthy found in other organs.

For these notes and her untiring care of the patient I am indebted to my very efficient resident, Dr. Emma J. Lucas, and for the opportunity of using the antitoxine to Dr. William E. Hughes and Dr. Carter, who furnished the material and made the injections.

Dr. John B. Roberts said: I have been much interested in Dr. Porter's account of the unsuccessful use of antitoxine in acute tetanus. I am inclined to believe, from what I have read, that most of the cases that have recovered have been rather mild cases, and that the more severe cases have not shown any very brilliant result from the use of such treatment.

Equino-varus with Dislocation of the Astragalus.—Dr. Thomas G. Morron exhibited a patient, aged twenty-two months, on whom he had operated for this condition. He had removed the astragalus from each foot.

The Radical Cure of Hernia by Bassini's Method.—Dr. John B. Drayer exhibited a patient showing the result of an operation which had been performed October 12th, on account of temporarily irreducible hernia and the inability to control the hernia properly by a truss. This operation had the advantage of not confining the patient to bed for a long time. It consisted practically in making a new inguinal canal. The hernia was exposed and the spermatic cord separated from the sac. The hernia was reduced and the sac tied off close within the abdominal cavity and the redundant portion cut away. The internal oblique and transversalis muscles, with the rectus, were then stitched to Poupart's ligament, the cord was placed over these muscles, and the skin and superficial fascia were placed over the cord. He used buried sutures of silkworm gut, which were allowed to remain.

Dr. James M. Barton said: On several occasions I have started to perform Halsted's or Bassini's operation, but when I have got to the ring I have found the hernia so old that there was practically no canal, one ring lying directly over the other, and, as it seemed to me impossible to perform either of these operations, I have performed the Macewen operation. In my earlier Macewen operations I cut off all but four or five inches of the sac, when it was very long, fearing there might be sloughing if I retained it all, but in the later operations I have used the entire sac, even when a foot long. I would ask Dr. Deaver if in these cases of large hernia, where the two rings practically correspond, he makes any attempt to do Halsted's or Bassini's operation?

Dr. Deaver said: In answer to Dr. Barton, I would state that I have done very few of the Bassini operations, but in such cases as Dr. Barton mentions I have done Barker's operation, without, however, obtaining a permanent radical cure. This operation consists principally in tying off the sae at the internal abdominal ring. As Dr. Barton has pointed out, I think there would be some difficulty in doing Bassini's operation.

# Reports on the Progress of Medicine.

#### PSYCHIATRY.

BY FREDERICK PETERSON, M.D.,
PATHOLOGIST TO THE NEW YORK CITY ASYLUMS;
PHYSICIAN TO THE RANDALL'S ISLAND INSTITUTION FOR IDIOTS.

Modification of Insanity by Intercurrent Cholera.—One of the interesting phenomena observed during residence in an asylum is the often remarkable effect upon the psychic condition produced by any severe intercurrent disease—such, for instance, as pneumonia, typhoid fever, erysipelas, and the like. It is rare, however, that an opportunity for the observation of this modification presents itself on so large a scale as it did recently in the Bonneval Asylum (Journal of Nervous and Mental Disease, September, 1893), where during an epidemic of cholera sixty immates were attacked, and notes were made of their mental condition as follows:

For convenience of observation the patients were divided into five groups—maniacs, melancholiacs, the partially delirious, the organically insane, and idiots.

In the case of maniacs it was shown that, during its severe periods, cholera caused all maniacal conditions, of whatever character and of however long standing, to disappear; but, on recovery, the mental derangement returned by degrees.

Cholera usually modified the melancholic conditions for the better, but too few cases had been examined to warrant any final conclusions

Persons slightly insane or melancholy had regained, to a greater or lesser degree, their mental soundness during the attack.

Those organically insane had not been affected mentally by the disease. In whatever case there had been maniacal excitement accompanying the delirium, this had disappeared entirely during the cholera attack. When delirium had accompanied a melancholy state, the latter had been more or less modified, but the delirium had remained.

One case had been that of a paralytic whose insanity had been of long standing and whose mind had not been perceptibly affected by the disease; but this single case proved nothing.

The idiots attacked had been too feeble-minded to afford a basis for determining results.

In every case, however, except the last, the patients had understood the danger of their condition, and had faced death calmly.

Puerperal Insanity a Toxemia.—Dr. Menzies, of the Rainbill Asylum at Liverpool (American Journal of Insanity, October, 1893), presents a very interesting study of a hundred and forty cases of puerperal insanity Of these, thirty cases were insanity of pregnancy, sixty-four insanity of parturition, and forty-six insanity of lactation. The author rightly says that these various periods merge so imperceptibly into one another that any division must be to a certain extent arbitrary. He applies the term insanity of pregnancy to cases in which mental alienation was noted before the birth of the last child,

and all that began two months after parturition he classifies as insanity of lactation,

While it is generally considered that puerperal insanity is apt to have a sudden onset, fifty-four per cent. of his cases presented prodromal symptoms. In all forms depression is the first manifestation, as a rule, in the form of sadness, distrust, apprehension, or religious awe. This period of depression may be of short duration or persist for months. States of depression are found in fifty-three per cent. of all pregnancy cases, in thirty-four per cent. of parturitional cases, and in seventy-four per cent. of lactational cases.

Pregnancy Types.—In nearly half the cases the patient imagines she is going to be killed or has committed the unpardonable sin, or else she combines the two ideas. In this type the delusion as to disloyalty on the part of the husband exists in but a small percentage. There are no distinctive mental features in this form by which we may distinguish it from other cases of melancholia. A physical examination is necessary. Mania of pregnancy, however, has distinct peculiarities, but it is rare and only eight of the author's cases presented this form. The chief diagnostic points of the insanity of pregnancy are: 1. Silent reserve and unsociability. 2. Strongly marked delusions of identity. 3. Religious or erotic impulse. 4. Rational performance of routine duties if the patient is left to her own resources.

Symptoms rarely present themselves before the fourth month of pregnancy, and most commonly develop in the fourth or fifth month.

Puerperal and Parturitional Types.—Delirious excitement is most usual, occurring in forty-six per cent. of the cases. Snicidal and homicidal tendencies are not uncommon. Among the delusions of puerperal delirium, the most frequent is that of fear of impending violent death; but false identity, religious ideas, and hallucinations of sight and hearing are common. Acute delirious mania was present in but two of the author's cases. The tendency to relapse after apparent improvement or convalescence is great, and relapse is often quite sudden. Eighteen per cent. of the cases developed in the first week after confinement, fifteen per cent. in the second week, forty per cent. in the first month, and fourteen per cent. in the second month.

Lactational Types.—The same symptoms occur here as in the other forms, but the order of frequency of the types is different. Thus twenty-four per cent. show melancholic delirium, fifty per cent. quiet, depressed states, twelve per cent. mania, and fourteen per cent. maniacal delirium.

Any given case of puerperal insanity, of whatever type, may pass through six stages: 1. Prodromal disturbance. 2. Early delirium. 3. Melancholia. 4. Stupor. 5. Mania. 6. Dementia. Many patients pass through all the first five and yet recover, but, generally speaking, the fewer the stages the better the prognosis.

As regards the recovery rate, it is high in insanity of the puerperal period, as is generally conceded. Seventy-five per cent. of the author's patients whose cases were of the parturitional type recovered, but only 43°3 per cent. of the pregnancy type, and 56°5 per cent. of the lactational type. In the cases of recovery the duration of treatment until recovery was as follows: Eighteen recovered in two months, twenty-one in four months, sixteen in six months, seventeen in a year, and twelve in over a year.

Twenty-one patients died. Of these, ten had general paresis, five insanity of the parturitional type, and six insanity of the lactational type. Of the last eleven, six had phthisis, one general pyæmia, one Schluckungspneumonie, one coma and convulsions, one exhaustion and diarrhœa, and one acute delirious mania.

Some valuable facts are brought out by the author in regard to certain questions often referred to in connection with insanity connected with childbearing.

Thus, in seventeen of the one hundred and forty cases the mother exinced a teeling of hostility to her child, but in only two was there an attempt to kill it; fourteen patients attempted suicide before their admission to the asylum, and thirty-one patients showed crotic tendencies. Erotism plays an important part in the early puerperal period. It generally develops after confinement, but sometimes before it. Indecent overtures and attempts at exposure are made, and in the delirions conditions filthy jokes and grossly vulgar details of private life are given.

As to the influence of the unmarried state upon the production of puerperal insanity, only ten of his patients were single women, and of these, seven had led dissolute lives previously. The author is opposed to the idea that the shame of exposure and the worry incident to illegitimate pregnancy are causes of puerperal insanity.

Ten cases in the series of a hundred and forty were cases of general paresis, and the author is doubtful as to whether the connection between pregnancy and general paresis should be considered purely accidental.

Another interesting fact is the course of labor in insanity. It is generally precipitate. The rapidity of delivery is very remarkable.

Probably the most valuable part of this paper is the discussion of the pathology of puerperal mania. Dr. Menzies advocates the very sensible theory that the cause is self-intoxication. The maternal excretion is overtaxed by the considerable excretion of waste products from the fœtus, accounting possibly for toxemia in the insanity of pregnancy. Delivery leaves the lymphatics choked with albuminous fluids of low vitality, which, if not excreted quickly, may change and poison the blood, in this way giving rise to the insanity of parturition. The drain of albumin in lactation possibly alters the chemical composition of the blood, and may thus give rise to the lactational type of insanity. These blood poisons engender the psychic symptoms naturally by their effects upon the intellectual substrata. In puerperal insanity a temperature of 101° F. is not at all uncommon, even in the lactational form. Cessation of the lochia invariably aggravates the mental condition, and involution is always retarded. There are waxy pallor, sallow skin, quick production of anæmia and wasting, and great destruction of hæmoglobin, all pointing to a blood condition and not to a cerebro-cortical disturbance. The universal benefit derived from a purge, the recognized objection to a drug like opium, which paralyzes osmosis, and the advantages of uterine douches, show that asylum physicians act up to the toxemic theory, whether they admit it or not.

Readers are referred to the original for a very careful elaboration of the self-intoxication theory, but the main points are given above.

As regards treatment, the author believes in hydrotherapy, purging, good feeding, stimulants, rarely a hypotic (either chloral or paraldehyde), rest in bed, hot uterine douches, and stopping the secretion of milk, according to the case and its condition. Intestinal antiseptics he believes to be of little or no use. If they are to be employed, let it be creasotal in doses of from half a drachm to a drachm thrice daily. Creolin offers some advantages possibly, but is not palatable.

The Ætiology of Puerperal Insanity.—Idanof, of Moscow, has made a study of fifty-three cases of puerperal insanity, an account of which is published in the Annales médico-psychologiques for May and June, 1893. They were all cases of the parturitional form. He divides the causes into predisposing and

exciting. In fifty-six per cent, heredity was marked, and fortyfive per cent, of the patients were primiparse. The author thinks infection occupies the first position as an exciting cause, and infection was certain in seventy per cent, of his cases. Eclampsia he also believes to be of an infectious nature. Emotional disturbances, he says, play an important part in causing puerperal insanity, and the percentage of such cases was twenty six.

Narcolepsy.—Böhm, in an inangural dissertation (Berlin, 1893), gives in detail the histories of four cases of this disorder observed in Mendel's clinic. Three were in females—aged, respectively, eleven, twelve, and thirty-one years—and one in a young man of eighteen years. In all his patients hysteria was marked, in two of the girls hystero-epilepsy existed, and in one of them there was also exophthalmic gottre.

Narcolepsy was first described by Gélineau as a disorder manifested by an intense desire for sleep, occurring at short intervals. The afflicted patient falls suddenly into a deep sleep, no matter what he may be doing at the time, and is not awakened by being called, although a light touch rouses him instantly. Hysterical symptoms are certainly very often combined with narcolepsy, even if the latter is not to be considered simply as a manifestation of hysteria. In the three females described by Böhm the narcolepsy was of the above-described character, but the young man's case had a somewhat different course, marked by symptoms of a stronger hysterical nature (once a forty-eight-hour somnolent condition, subsequently a sleep of two weeks' duration, morbid movements of the eyelids and eyeballs, and limitation of the visual fields). He recovered suddenly after an attack of nose-bleed.

Traumatic Psychoses. - Jacobson, in the Nordiskt med. Arkiv, No. 13, 1893, gives a study of seventeen cases of cerebral disorder due to serious traumatism to the head, in which it is shown that, in the strict sense of the term, a traumatic psychosis does not exist-that is to say, a malady easily distintinguished from other forms of mental disease. But it is true that the mental symptoms following head injuries often present analogies in a series of cases. The form of psychical disturbance is usually mental confusion, and this may be hallucinatory, maniacal, or stuporous, or even a chronic dementia with or without motor paralysis. He has observed several cases of general paresis that had been preceded by traumatism to the head, but he can not say concerning a single one of them that the head injury was the actual cause of the disease. In cases where syphilitic infection exists before the traumatism the ætiological rôle of the latter factor must remain doubtful. It may be supposed that, where the brain is already altered by syphilitic lesions, injuries to the head may more easily provoke psychic manifestations than under ordinary conditions.

The Chemistry of Digestion in Pellagrous Insanity.—Agostini has studied gastric digestion in twenty-two cases of pellagrous insanity (Prag. med. Woch., 1893, No. 32) to determine the quantity of free nitric acid and the total acidity, to examine the peptones and pathological organic acids, and to observe the motor capabilities of the stomach. He found that gastric digestion was slow and inefficient in these cases. There was a diminution in peptones and in the total acidity. There was fifty per cent. less of free nitric acid. Often there were abnormal organic acids, especially lactic acid, and there was weakening of the motor functions of the stomach, with a secretion of mucus in abnormal quantity. Therapeutically, the author recommends lavage with salt water and the administration of nitric acid after meals.

The Bactericidal and Toxic Action of the Blood of the Insane.—In the Rivista sper. di freniatria e di med. legale, vol. xviii, d'Abundo describes experiments made with the blood

of demented persons—paralytics, melancholiaes, paranoiaes, maniaes, idiots, and persons with pellagrous insanity—relative to its toxicity and bactericidal power. Eighty six observations were made. The toxicity was determined by the injection of defibrinated serum into the auricular veins of rabbits, while the bactericidal power was tested upon the anthrax bacillus. Ten cubic centimetres to the kilogramme of normal blood kills rabbits by acute intoxication. He found that the toxicity and bactericidal power of the blood in depressed conditions was diminished, but in all other forms of insanity it was increased.

General Paresis in Children .- Wiglesworth reports in the Journal of Mental Science for July, 1893, three cases of his own of general paresis in children and five others collected from literature. The youngest patient was twelve, the oldest sixteen years old. The average duration of the disease was four years and a half-a longer average than in adults. Five of the patients were girls and three were boys. In only one patient were there grandiose ideas. All the other patients presented the dementia type of the disease. The signs of puberty failed to appear, none of the girls menstruated, and bodily growth seemed to be arrested. Excessive emaciation was striking. In two of the author's cases autopsies were made. The extreme atrophy of the brain was very noteworthy. Hereditary tendency was traced in four cases, and in two others marked alcoholism existed in the parents. The question of the relation of syphilis to general paresis is especially important in youth, and it is interesting to note that Wiglesworth reports but three of these as affected with syphilitic disease. In two patients trauma to the head seemed to have been an exciting factor. The writer then describes the cases of two lads, each aged eighteen years, who had general paresis, and in an appended note the case of still another juvenile who died at sixteen years of age with general paresis. Altogether, then, there were eleven patients under eighteen years of age.

Folie a deux.—In the Annales médico-psychologiques for May and June, 1893, Arnaud has published a study of folie à deux based upon cases recorded in French literature and upon three cases observed by himself. He divides such cases clinically into three groups: 1. Imposed insanity (folie imposée), characterized by the unusually small mental resistance of the second to the first attacked. 2. Simultaneous insanity (folie simultanée), in which natural proclivity, environment, and corresponding atiological factors affect the two persons in the same manner. 3. A form in which the resistance of the second affected is at its maximum, and this patient is overcome only after a long battle, which finally exhausts his faculty of resistance.

There are three factors common to all forms of induced insanity—viz., a similar predisposition, long-continued and great intimacy of the two patients, and, lastly, a certain possibility or appearance of probability in the insane ideas. It is because of this last factor that most cases of folic à deux thus far published are of the character of paranoia with persecutory ideas. In all these cases there must exist an intellectual superiority of the first over the second patient. In the first form mentioned above, separation of the two patients gives the best therapeutic results; in the second form separation has no specially curative effect; in the third category, the second patient is apt to suffer in some different way.

In the Finska Lakaresāllskapets Handl., vol. xxxiii, part 5, Hongberg details a case of folie à deux. A midwife, aged thirty-four years, with no hereditary taint, in good health, visited a married sister in Helsingfors. While there she began to have delusions that she was guilty of sins that must do injury to others, and that she was engaged to some imaginary person of high social position. At a second visit, a year later, she still

had the same ideas. After leaving, at the end of this visit, she began a close correspondence with her sister, and her letters were chiefly made up of complaints of intrigues and persecution. At this time she was also the subject of hallucinations. Shortly afterward she was sent to the asylum at Lappwik. The second patient, the married sister, was twenty nine years of age. At the first visit of her insane sister she took great trouble to combat the latter's delusions and to show how groundless they were. Her husband was taken ill with pneumonia, and she was much reduced in health by constant nursing, shortly after her insane sister's departure. She then became depressed and was the subject of delusions that the secret police were after her and intriguing against her. She then sought the author and told him how both she and her sister were persecuted. She showed evidence of hallucinations and was taken to the asylum. Both patients had then become persecutory paranoiaes, and the second was clearly suffering from induced insanity of the imposed form.

[In the Alienist and Neurologist for January, 1890, the reporter published four cases of folie à deux observed by him, one in considerable detail, and in that paper called attention to the fact that for the development of folie à deux the essentials were intimacy of the affected persons and plausibility of the insane ideas. He showed, further, that it was on this account that sisters were more apt to become victims because of their greater intimacy, and that delusions of a suspicious and persecutory nature, because more readily given credence, were more easily imposed upon a close associate. Hence the greater frequency of folie à deux among sisters, and the usual form of persecutory paranoia.]

Hystero-epilepsy and Insanity in a Boy caused by Bitter-almond Poisoning .- Brugia (Il manicomio, vol. viii, Nos. 2, 3) relates the case of a boy aged eight years, in perfect health, without hereditary taint, who was poisoned by drinking a considerable quantity of essence of bitter almonds. The intoxication was characterized by general cyanosis, deep coma, and tonic and clonic spasms. He recovered from the immediate effects promptly, but suffered subsequently from irregularly repeated convulsions, and was retarded both in physical and in mental development. His character became much changed. He became morally degenerated, was frequently brought into conflict with the law, and finally, on account of more frequent convulsions, was committed to the asylum at the age of twenty years. Here he was found to have hystero-epilepsy, and the seizures were marked by loss of consciousness and right-sided hemianæsthesia and hemianalgesia. The permanent symptoms were diminished sensibility and loss of taste, smell, and hearing upon the right side, together with diminution of the right visual field. There was pronounced moral and mental weakness, with a tendency to impulsive acts.

A Psychopathic Epidemic in Russia.—Ssikozski describes (Universitelskija Isujestija, 1893; Neurolog. Centralbl., July 1, 1893) a peculiar religious movement that took place in the winter of 1891—'92 in the province of Kiev. The author was sent as an insanity expert and member of a commission to investigate the matter. It was determined that the originator of the movement was insane, and that most of his followers presented pathological evidences on the side of the nervous system and psychic functions. Hence he designated the movement as a psychopathic epidemic.

The originator was a Russian, from a country town, aged forty-five years, with intemperate ancestors, and himself given to drink until the age of forty years. He then gave up orthodox beliefs, went over to the sect of Stundists, stopped drinking, followed zealously the religious rites of the sect, and often went into a condition of ecstasy. A few years later he began

to suffer from hallucinations of smell and general sensibility. He perceived extremely pleasant perfumes, which were comparable to no earthly aroma. This was the smell of the Holy Ghost. During prayer he experienced a remarkable feeling of joy and of bodily lightness, as though he were floating in the air. Then he conceived fixed ideas-that he was possessed of the Holy Ghost, that he was Jesus Christ, the Saviour of the world, that the Bible held prophecies relating to him, and so forth. He would fall into states of excitement and improvise sermons. He obtained numerous followers, who consisted of the peasant population of several hamlets in the province of Kiev. They were convinced of the truth of their leader's statements, were exalted and joyful, sold their possessions, gave up work, purchased holiday attire and ornaments, bought candies and sugar to give to the poor, and made each other visits as on great holidays. They looked upon their insane leader as the Saviour of the world, in which there should soon be new regulations; no one should die, and no one should have need to work or to care for the future, for God would care for them all. Most of them suffered from hallucinations of the sense of smell. The author came personally into contact with hundreds of these people, and states that eighty per cent. of them bad sensory illusions. They perceived extremely agreeable odors, which they described as pertaining to God and heaven. They would smell of their hands and other objects in order to find out the origin of the aroma, which they ascribed to the Holy Ghost. Many had the feeling of remarkable bodily lightness, as if floating in the air. Some heard the voice of God, the whispering of the Holy Ghost, saw heaven open before them, and so on. Many were taken with convulsions, manifestly of an hysterical character. The congregations were always noisy and exalted, many falling to the earth, others jumping, striking themselves on the breast, shouting inarticulately, the women undressing themselves and becoming erotically excited. some a peculiar form of verbigeration was observed. They would imitate a conversation, but it consisted of incomprehensible, senseless sounds, which they believed to be a language spoken by some people somewhere. In some cases there was complete analgesia during ecstatic conditions. Most of them were emaciated and anamic. The epidemic was overcome by the authorities, who forbade the congregating of these people. Those who were most insane were shut up in asylums, and the hysterical persons were sent to hospitals and convents. Such as exhibited criminal tendencies were sent away. Exact statistics as to the numbers thus treated are wanting.

# Miscellany.

The Treatment of Acute Gout.—The following is the substance of an editorial article that appeared in the Union médicale for December 9, 1893: Suppose a patient at the onset of his first attack of gout or of one of his early attacks; what is to be done? Perhaps it would be in consonance with sound practice to say to the patient, with Nothnagel: "Overcome pain by intellectual effort," or, simpler still, repeat to him Sydenham's maxim: "Patience and flannel." But this platonic sort of treatment would involve the risk of damaging both the physician and bis patient at the same time, so something must be done and that quickly. The local treatment is easy. It consists in wrapping the diseased part in cotton and immobilizing it in an elevated posture. It may be treated by the application of an ointment of one part of cocaine hydrochloride to sixty parts of vaseline or oil of sweet almonds, or

by painting it with a solution of from one to two parts of menthol in ten parts of alcohol, or by the application of a lotion of fifteen parts of menthol to a hundred and twenty parts of chloroform. Iodoformized collodion also has been recommended. The thing to do is to change the topical applications; this will occupy the patient's mind, and, moreover, what fails in one case succeeds in another, without anybody being able to say why. Internally, if the kidneys are sound, the great remedy is colchicum; in Lécorché's words, "it is par excellence the specific for gout, and it may and should be used in the treatment of this disease in the acute stage." The patient should never take colchicum without being closely watched by his physician, and it is well to warn him of the danger of poisoning to which he would expose himself by increasing the dose in order to shorten the period of his confinement. Sodium salicylate is never so good as colchicum, and sometimes it is very badly borne. There is no use in waiting for the tardy action of lithine in gout that is manifestly acute.

The internal treatment may be outlined as follows: 1. Slight purging every morning with saline waters. 2. To begin with, a moderately large dose of colchicum, then doses of two thirds the amount. The attack may be accompanied by high fever; in that case from five to eight grains of quinine sulphate may be given daily. If the pain is excessive, morphine may be given by subcutaneous injection. At the beginning of the attack, especially if there is fever, only very light food should be taken, and even complete abstinence may be indicated. The patient may be told to drink copiously of alkaline mineral waters, such as those of Vals and especially Contrexéville, and this will often prevent dysuria. When there is no longer any spontaneous pain, the patient should be kept at rest and told that premature exertion may bring on a fresh attack. Massage may be used, but without the slightest violence. It is important never to use local bloodletting, tincture of iodine, blisters, cold water upon the joints, or antipyrine internally.

The patient should be questioned minutely in regard to any indication of kidney disease; if he has any signs of gravel, it, a fortiori, he states that he urinates often, especially at night, that he gets up often to make water, etc., or if there is a large amount of albumin in the urine, evacuants, especially those that act on the kidneys, are contraindicated; then it will be well to prescribe, in addition to the local treatment: 1. An exclusive milk diet. 2. A drink made by boiling 150 grains of the dried flowers of Vicia faba and from 60 to 150 grains of sodium benzoate in a quart of milk, the whole of which is to be taken in the course of twenty-four hours. 3. The administration of four grains of quinine sulphate night and morning. 4. A saline purgative every morning. By so doing, says the writer naively, you may be benefiting your gouty patient more slowly, but at least you are sure of not poisoning him.

A Precaution in the Use of Cocaine as an Anæsthetic.—
In a recent number of the Centralblatt für Chinurgie we find an abstract of an article by Dr. Gauthier, published in the Gazette des hôpitaux, on a means of preventing the unfavorable after-effects of cocaine when it is used as a local amesthetic by injection. This consists in the addition of one drop of a one-per-cent, solution of nitroglycerin to the injection. The author goes on to say that nitroglycerin dilates the blood-vessels of the brain in the same way that amyl nitrite does; in the course of a few minutes after the injection of two or three drops of a one-per-cent, alcoholic solution the skin of the face is seen to grow red and hot, the conjunctiva becomes injected, and the patient complains that his head feels as if it were going to burst. M. Gauthier has taken advantage of this action, antagonistic to that of cocaine, for the last two years.

# THE NEW YORK MEDICAL JOURNAL, JANUARY 13, 1894.

## Rectures and Addresses.

## THE SURGERY OF THE HAND.\*

BY ROBERT ABBE, M. D.,

SURGEON TO NT. LUKE'S HOSPITAL;
CONSULTING SURGEON TO THE HOSPITAL FOR THE RUPTURED AND CRIPPLED;
PROFESSOR OF SURGERT IN
THE NEW YORE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

My interest in the surgery of the hand was first stimulated in 1875, when, in assisting Dr. Weir in a resection of the wrist, I read Liston's enthusiastic and scientific article upon that subject, in which he spoke of the marvelous mechanical perfection of this particular joint.

No one can contemplate the perfect hand without wonderment and admiration, but, like the use of our eyes and ears, we think little about it unless its use is impaired.

Many of the surgical troubles that occur to the hand—fractures, sprains, etc.—have their counterpart elsewhere in the body, and we shall not consider these this evening. Nevertheless, there is great need of wider knowledge by general practitioners of the importance and gravity of such common troubles as poisoned cuts and pin pricks of the thumb and little finger, the suppurative inflammation from which spreads along the tendon sheaths to the common bursa of all the flexor tendons above and below the wrist. This causes permanent loss of usefulness of more hands than are destroyed by all other causes together. A bad result can only be prevented by quick use of the knife and antiseptics.

Of very great interest among hand troubles, of which I find a widespread ignorance among physicians, is one which has attracted my attention specially during the last twelve or fifteen years, and which is illustrated by some of the charts here displayed—namely, Dupuytren's contraction of the palmar fascia.

The general surgical aspect of the malady has received most careful consideration by Mr. William Adams, whose very large experience in this particular disease has rendered him the first authority upon the subject, and it is needless for me to more than refer to the second edition of his valuable work, issued last year, for most of the essential points upon it. There are some points, however, that have come within the scope of my experience on which my judgment differs somewhat from his, and to these I will direct especial attention.

In two previous articles written by me upon this subject, first in 1884 (see the New York Medical Journal, April 19th and 26th, and later in the Medical Record, March 3, 1888), I proposed a theory of its causation which was entirely at variance with the gouty theory generally accepted and since reiterated by Mr. Adams.

Reasoning from numerous cases of the neuroses and neuralgias which the patients with Dupuytren's contraction were often subject to, I satisfied my own mind, at least, that there was a strong probability that traumatism of the

nerve ends in the palm, reflected to the central nervous system and thence to the opposite hand, would perfectly account for the course of events as seen in this class of cases.

Mr. Adams and Dr. Keen, of Philadelphia, have both lingered over the theory of its gouty origin, strongly impressed by certain phases of rheumatic development in the affected hands, and by the occasional hereditary tendency of the disease.

My own experience, based at that time upon about twenty-five private cases and fifteen additional public hospital cases, led me to discard the gouty theory because of the almost universal absence of gouty inheritance of the patients who came under my observation. It was not rare to find a history of rheumatism in the families of the patients, but extremely rare to find a case of typical gout.

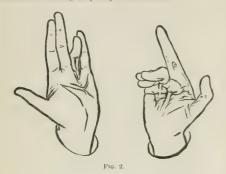

In both my papers I detailed many cases of striking neuralgias and neuroses incident to the course of the contracted fingers. It is curious to me that Mr. Adams is able to say that in the course of his experience in England he has never met with any such cases of painful neuralgias and neurotic affections extending to the shoulders and spine. He naïvely remarks that while I have "asserted that in English society gout is an almost universal legacy, and in America typical gout comparatively rare, but rheumatism more common," he "can not help thinking that distressingly painful neuralgias and various neurotic affections are more common in America than in England." My subsequent experience, based on an additional twenty-five cases in private practice during the last four years, into the histories of which I have been able to search, leads me further away than ever from the presumption of gouty origin. A few striking cases of neuralgias have occurred among these, but none so pronounced as several that are quoted in my first two papers. Several cases in my experience have resulted from distinct traumatism and scars.

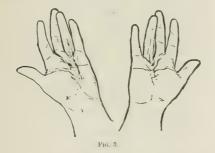

I shall briefly recount a few typical cases to illustrate my position, and I shall be greatly surprised if the future experience of others having their attention called to these associated symptoms will not also reveal many that have been overlooked by them. Except for the typical gouty manifestations in the feet and hands, it is easy to say gout is the cause of many clinical symptoms and hard to prove it in these contracted finger cases. The trouble is certainly

<sup>\*</sup> The Wesley M. Carpenter lecture, delivered before the New York Academy of Medicine, November 20, 1893.

absolutely rebellious to antarthritic remedies, and does not come generally in gouty subjects. There is no exact analogy to this palmar contraction in gouty manifestations elsewhere. Tophi are never seen in these palmar contractions, no matter how long they may have existed.

The theory of gout, so far as I can see, is purely an assumption. On the other hand, the disease affects a member whose tissues are highly endowed with nerve ends. It is associated with pure neuralgias. Its neuralgias are often relieved as if by magic by an operation on the bands. It prefers to attack the ring and little fingers, the most subject to bruises.

"The joints of these hands are generally in a healthy condition," says Mr. Adams. I myself have but once seen a truly gouty knuckle in these patients. The fact that many patients can refer the contracting band to injury and sometimes show scars is an argument in favor of this probable causation in all cases—i.e., traumatism. Such cases as the following are not uncommon:

Ten years ago a patient was precipitated down an elevator, hanging on the chain for two stories. He did not experience any special bruise, except that the skin was slightly cut on the left hand and torn a little on the right. Three or four years later the ring finger in each was drawn down a little in the palm, the left soon touching it.

Several of my patients attributed their contractions to the driving of horses; others to boat-rowing and other injuries. One typical bruise may be illustrated as follows:

Mr. O., aged fifty-three years, a most intelligent observer of his family history, denies rheumatism or gout on either side

among his ancestors, and is conversant with his family history for several generations back. Ten years before this trouble began he used the palm of his right hand, on the little-finger side, to knock up the lever of a heavy safe door, and has kept up the practice ever since. In two or three years the contraction began in the little finger of that hand, and it has progressed ever since. Dull aching was noticed in the morning at the seat of trouble. Two years later the knuckles of all his joints of the affected hand began to act as if subject to subacute rheumatism and two years ago the left-hand knuckles of the corresponding fingers became red, swollen, and showed some disposition to ache. This phase of rheumatism, as pointed out and fully illustrated in my first paper, is a distinct neurosis.\*

An interesting illustration of neurosis was shown by Mr. W., who had a sharp band developed in the middle finger ten years before. Some contraction had also developed in the left palm later. The patient emphasized a curious neurosis that had been present in the right arm most of the time, especially on awakening and for some time afterward-i. e., a sense of great increase in size, as if the shoulder and arm were distended to twice their natural size, giving a strange and unnatural feeling; occasionally he has pain about the left shoulder. In 1885 I operated, dissecting out the band throughout the palm. There were three purplish nodular swellings along this cord. It was done under cocaine and painless. The finger came out perfectly straight. Two years and a half later the hand was absolutely free from contraction; the fingers could be even bent backward a little; the cicatrix was soft and white; he had had no pain for two years. The neurosis of his arm entirely disappeared. Moreover, the left-hand bands, that had not been operated on, became softened a little and gave no trouble.

A second case was of much interest. Dr. W., a distinguished physician of this city, with absolutely no inheritance of rheumatism or gout, attributes his contractions to the use of the rough head of a cane. His father also had had the same trouble. In his right hand, for fourteen years, he had a contracted ring finger, bending down well toward the palm. Recently he had suffered from brachial neuralgia and deltoid and cervical pains, like lumbago, on the affected side. His left hand began, seven years after the right, at the same point precisely. There was a burning sensation in the palm, and commencing neuralgia of his arm. The right hand showed bands running to the little and ring fingers; the left, bands, faintly outlined, going to the same fingers.

This illustrates the almost universal fact that both hands are very rarely affected at the same time; that one follows the other at an interval even of years, and that the corre-

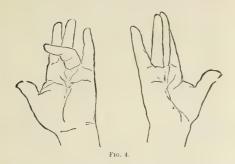

\* Of other cases attributable to accidents I would mention that of Mr. P. K., who, climbing a ladder, had a spiked piece of frozen mortar clinging to a round pierce his palm over the ring finger. The callus never went away entirely. Typical Dupuytren contraction ensued. After two or three years progressive weakness of the ulnar fingers ensued, diminishing his grip and associated with writer's cramp.

In another, a civil engineer had a long series of stakes to put into the ground, and pressed them hard with his palm. Next day he had a sore palm, and dates his contraction from that.

I have seen but one case where Dupuytren contraction was secondary to neuritis.

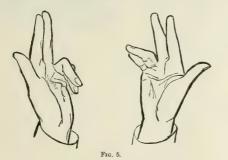

A man of thirty-seven years had his forearm caught between two cars, so as to jam the elbow at one end and the palm at the other. Subsequently he had pain of ulnar and progressive partial paresis, with atrophy of the thenar eminence and development of true Dupuytren contraction of the fascia over the ring and little fingers, which I dissected out with much relief, but ulnar neuralgia with swollen nerve, easily felt at the elbow, continued as long as he was under observation.

sponding fingers on the ulnar or radial side—usually the ulnar—take much the same position in both hands, as is well illustrated in Figs. 4 and 5. These points are an argu-

ment in favor of the reflex action of one hand through a corresponding nerve to the opposite hand.

There was more or less swelling of the knuckles of both hands, resembling rheumatism. In 1889 I cut out the band in the right-hand finger, and made two transverse cuts to release the little finger. Six months later Dr. W. came to see about having the left hand cut, reporting that the operation on the right hand had been most satisfactory; that he had since had but little pain in the shoulder, and could put his arm forward without inducing pain. The left hand had been recently giving neuralgia of the ulnar side of the forearm and numbness of the

little finger. Two years later he made the following graphic and convincing narrative of his pains which had been present at first:

- 1. Has had no knuckle swelling or suggestion of rheumatism.
- 2. There has been no pain at all in the right hand.
- The neuralgia and pain in the right cervical region have not returned.
- Until lately there has been no pain whatever in the right shoulder.
- The burning of the left palm disappeared after the operation on the right hand, and has never returned.
- 6. The pain that was slight but present in the left arm before two years ago, no operation having been done here, has increased so as to be unpleasant, resembling sciatic neuralgis, not limited to any muscle, but distributed in the back of the arm and the ulnar side of the forearm. The arm aches when raised to the horizontal, and has an unnatural feeling of heaviness.
  - 7. Altogether, the left has been the bad arm this year, while had been made, was straight and supple.

before the operation on the right, that one was the chief seat of trouble.

I now operated upon the left hand, and there has since been absolutely no return of trouble. The right hand illustrated how well the excision method of operation had done on the ring finger. The cicatrix was fine and free from recontraction. The little finger on which crosscuts were employed recontracted somewhat.

A. B. was a car conductor, whose left index finger had drawn down into the palm and interfered seriously with his work. He attributed it to former hard plowing and hoeing. He had neuralgic rheumatism across the shoulders, so persistent that he got his coat on with difficulty. I made five transverse cuts and released the fingers perfectly. Two months later he reported himself absolutely well and free from pain, having worked since ten days after the operation.

In 1888 I operated on A. C., aged fifty-three years, for Dupuytren's contraction, which he attributed to a strain while turning a stopcock firmly some years before, when he heard a snap as if something was breaking in his palm. The palm puffed up, and then the swelling slowly disappeared, the palmar contraction following fifteen months afterward. The left showed a knot of contraction in identically the same place as the opposite. Pain had commenced eight months before I saw him—a deep-seated neuralgic pain which made him think he had rheumatism. After the operation his pain disappeared.

Regarding Methods of Operation. — Following Mr. Adams's urgent advice, the tendency has been to resort to the subcutaneous division of the bands at several points in the palm. This method was uniformly resorted to by me in the early years of my experience. Finding many recontractions, and believing that the absolute safety of good surgical work enabled one to cut out and get permanently rid of the offending band of diseased fascia, I have during the last few years resorted in most cases to excision. The results have been better than by subcutaneous division in my hands. The operative procedure is thorough, safe, and exact. It can be done painlessly and bloodlessly with cocaine anæsthesia combined with Esmarch's bandage, and leaves soft linear scars.

The relative merits of excision and subcutaneous division have been illustrated by some of my cases in whom both methods were tried; for instance:

A lawyer from Indiana, whom I saw in 1887, had his right middle finger drawn down for twelve years, and the left became involved five years later. Three years before I saw him he had had a cross-incision of the right-hand band in the palm which brought the fingers straight, and it was useful for a time, though it afterward required another operation. This time the subcutaneous incisions were made by an able surgeon. It soon began to draw down again when the splint was removed. Six months later the left hand was operated upon by subcutaneous incisions. Contraction had been progressive ever since these wounds were healed. I operated by linear extirpation of the right-hand band, not exposing the tendon or nerves. On the left hand the cicatricial and fascial contractions had matted the tissues of the palms. I made cross sections at seven points, making lozenge-shaped cuts when the finger was straightened. This left the finger free. The result was all that could be desired in both hands at the time. Three years later the left hand had undergone recontraction of the ring finger, which had been crosscut, while the right, where excision of the band

This proved incontrovertibly to my mind the superiority of excision. I then excised the band that had reformed in the left hand, which had become more prominent, and was able to release the fingers perfectly. Two years later a perfect result was shown from both operations. Five years had thus elapsed without recontraction of the first excised bands.

A tumefied condition of the fascial band often precedes the contracted stage, and can be readily cut across by open incision, after which the wound melts away invariably, though in a year or two the band is apt to recontract through the scar.

This dissolving of the tumefied cord when severed is as if the nerve filaments being cut, the path of irritation is broken, and the products of inflammation are quickly absorbed.

I now give decided preference to the cutting out of contracted bands, which, though a somewhat delicate operation to do, is thorough and enduring in its results. Nowhere is the use of cocaine more satisfactory. Yet I have found, as has been observed also by others, that, from some yet unexplained cause, cocaine will occasionally yield very slight anæsthesia. I have seen this on two or three occasions only. A fine hypodermic needle must be used, and a two-per-cent. solution of cocaine. Not more than ten or twelve drops will be needed if properly placed in the derma at points one third of an inch apart along the proposed incision over the band. There will always be found a layer of fat between the tendon sheath and fascia. Interrupted fine silk sutures should adapt the cut edges exactly.

A narrow strip of cleansed gutta percha or protective is laid along the cut and small compresses of damp gauze laid an inch deep over this. Over all a square of thin gutta-percha tissue will keep the dressing damp and favor the drainage of the capillary oozing from the cut. A firm bandage should be applied before the Esmarch bandage is taken off.

The completed operation and dressing is done within twenty minutes, which I have found to be about the limit of time that most patients can comfortably bear a snug Esmarch bandage.

The first dressing should be changed in twenty-four hours. The second on the fourth day, when stitches may be removed.

Contrary to the custom of Mr. Adams, who puts on a straight splint at once, I have found it better to let the fingers assume a comfortably correct position, under a dressing without splint (which will often induce pain by overstretching), and I put on no splint until a week has gone by and the parts are healed.

Although I have records in my private note book of fifty cases of Dupuytren contraction, representing about that number of operations, I have never seen a case of suppuration after operation, although most of those of the last four years have been excised.

The paralytic and inflammatory deformities of the hand—so-called "main en griff i"—are to be carefully distinguished from Dupuytren contraction before operation, the tendons in such cases being contracted but

buried in the flat palm and not raised like the bands of the latter.

Contractions simulating Dupuytren's.—Twice I have seen children with the little and ring fingers of each hand drawn down to the palm, looking like a Dupuytren's contraction, but purely of reflex origin. One case, seen five years ago, has lately been reported by the child's father as almost entirely straightened with time.

Another quite frequent deformity resembling a Dupuytren's contraction is seen in the little finger curved by reason of a congenitally short skin on its palmar side preventing its being straightened out as its neighbors. On manipulating it, one readily feels that there is no band under the skin.

I have seen one such finger with a double twist giving it a spiral curve toward its neighbor.

The palm is occasionally traversed by bands of congenitally short skin underlaid by somewhat limiting bands

—not, however, of palmar fascia. This is well illustrated by the annexed Fig. 6, showing the hand of a young lady whose piano playing was limited by inability to stretch the fingers far enough. This was greatly improved by several subcutaneous cuts.

To completely remedy these defects is not possible, but much may be done toward that end by crosscuts of the short skin, al-

Fig. 6.

lowing the lozenge-shaped gaps to granulate and be stretched later. This I have done in several cases and acquired a soft scar.

Neuroses of the Hand.—These belong mostly to the province of the neurologist, but some, being of surgical interest, may be mentioned:

An intelligent lady of forty-five years ran a threaded needle, head first, into the middle of her middle finger on its palmar side. She experienced not much pain, but an entirely disproprtionate shock to her nervous system. She was bewildered and could not collect her thoughts for a few minutes. The needle being tightly stuck in, she had to use force and pulled it with her teeth. She observed a stringy fiber came with it, which her doctor said was a nerve. She walked home an hour later, but was overcome by bewildered feelings. She lost her memory and found herself leaning against a house some distance away.

Her nervousness continued, and on the second night she awoke like a mad person with intense pain and a swollen finger. Suppuration, erysipelas, and pyremia followed. One night she awoke with aphasia and left hemiplegia, and did not recover speech for six weeks.

When convalescing she had spasmodic contraction of the face, arms, and legs during dressing of the hand. The healthy side became hyperæsthetic. It was three months from the accident before she began to walk. She still mixed her words, and when I saw her two years later she was in an overwrought nervous state with a hand unfit for manual work. Memory.

which had always been good before the accident, was still capricious. For example, she would forget in ten minutes all I had asked and said to her, but a week later it would recur clearly to her. She used wrong words and was not at the time conscious of it, but in half a minute realized she had spoken falsely.

When she began to speak after her sudden aphasia she had to learn over again the use of most words and the meaning of many. She still mixed up words in a sentence.

Such is the history of a striking case of shock to the central nervous system from a slight nerve injury of the hand.

A boy was brought to me with the ring and middle fingers of his hand half closed into his palm. There was no Dupuytren contraction of the fascia. He had been playing at jumping over posts some years before and bent down the middle fingers, straining the knuckles, which enlarged, with subsequently some rigidity. Later the same pain and stiffness were reflected to the opposite hand with occasional neuralgia of the shoulders. He had flexor cramps when gripping a hammer, hoe, or rake.

Several cases narrated further on represent also neuroses from traumatisms.

Incidentally one may meet these conditions with hammer palsy, artisan's cramp, or musician's cramps, many of which I have seen. Among them, one more striking than another is that of a young lady, a violinist, who, being in perfect health, was assigned by her teacher to play a concerto in public. Time being limited, she practiced one staccato movement, which was new to her, for two hours in succession, at the end of which time she broke down completely. Her hand was useless. There was complete muscular or nerve exhaustion. She was unable to write or use her violin. Later she had insufficiency of the eye muscles, requiring prisms, and flat foot, requiring her to use crutches and have a metal arch put into her shoe.

Seven years have passed and she has never regained nervous force enough to control her violin bow, or to write more than ten minutes without her hand giving out.

These few illustrative cases, chosen from many, suffice to show the intimate relation between many cases of hand troubles involving nerve ends and widespread disturbances of the system.

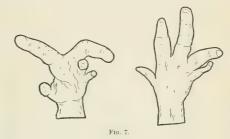

Tumors.—Of more special surgical interest are tumors of the hand and fingers, of which from many I will narrate three or four of special interest. It is in the hand that the smallest tumors are often the most troublesome, because conspicuous. I have notes of one little tumor as large as a small pea on the end of the thumb in a woman who had been prevented from sewing by it, owing to pain on pressure with further pain in the arm. It was in and below the deep layer of the derma, and on being dissected out proved to be a purplish-looking spindle-celled sarcoma, denominated by Paget painful subcutaneous sarcoma. A second and larger one in another patient grew in the center of the palm.

I have had four such tumors of the hand—two above the wrist—so painful on being struck that they caused the hand to drop anything that the patient might be carrying.

One which I dissected out ten years ago was a typical sarcoma, and had not recurred at the end of eight years. Nor have the others returned as far as I know. Another

tumor at the base of the index was as large as a walnut, was soft enough to give a striking sense of fluctuation, but proved to be a pure fibroma with soft stroma.

In the palm one occasionally sees small hernias of the sheaths of the tendons buried in the fat of the palm, little cysts filled with transparent jelly and with very small connection with the sheath. These are like weeping sinews, so common on the back of the wrist, but can not be dissipated by a blow. I have seen them disappear without treatment, but this is so rare that one should dissect them out if they give trouble. Such a one I recently dissected out from the fat of the palm at the root of the ring finger, where it had given annoyance.

Hypertrophy of the Fingers.—Hypertrophy of the knuckles, very well described in Tillmann's Surgery (Leipsic, 1892), is an epiphysial hyperostosis, with elongation as well as broadening of the bones of some of the fingers. Others on the same hand often remain normal. The drawings (Fig. 7) are taken from a photograph of a lad sent to me from a physician in Maine. The great toe and the second toe showed the same extraordinary enlargement.

Trigger Finger.—I fancy it may be such a growth that causes the curious trouble denominated (trigger) "snap-finger," of which I reported

Fig. 8. Fig. 9.

five cases, with illustrations, some years since (see Figs. 8, 9, 10, and 11, here published by permission of the *Medical News*, in which they originally appeared). The patient closes all his fingers in the palm, and on opening them finds

that one will stay shut and can only be opened by using the other hand to effect it, when it flies open like a knifeblade with a snap.

It is said to be due to a tumefied condition of a point of the tendon, making a bulbous enlargement that catches

under the ligament at the base of the finger. One such case is reported as being capable of dissection and relief. In my cases there was no perceptible swelling and all recovered after a few months, part of which time they were

kept on a little wood splint with pad pressure, which prevented friction and irritation.

Of particular importance I will men-

tion two deformities of the end joint of the fingers, happening from slight accident, which need the earliest surgical care and admit of most particular work.

Drop Finger.—Two cases illustrate what I would call "drop finger." Both happened from apparently insignificant causes:

In one, a lady was taking off a stocking, and pushing it down the side of her leg with the tips of her fingers, suddenly found the end joint of her ring finger had given way and hung at right angles to the finger, powerless. With her other hand she could straighten it, but was unable to support it. It appeared to have nothing but skin over the joint to hold it up. The extensor tendon, where it thins out disproportionally to its size above,

had torn away from its delicate attachment to the base of the last joint.

In a fortnight the joint became red and tender; a sharp, shooting pain extended from the knuckle to the wrist, forearm, arm, shoulder, and back of the neck. It was often severe enough to make her wholly sick.

She volunteered the statement that a fortnight after the accident the same joint of the other hand pained her when using it. This pain lingered six months after, when I first saw her. The injured hand was quite disabled on that account. It was tender if touched, ached if used, and if struck by mishap it "made her sick all over."

It was now impossible to straighten it on account of the inflammatory sealing up of the torn capsule. I therefore resected the joint and made a solid, straight, and useful finger. When it was healed she was free from pain. I have to-day seen her, more than five years since operation, and she has not since had pain and uses the finger as if it were never hurt.

The second case in which I operated was on a prominent architect, whose ring finger dropped useless at the last joint from the slight pressure of his finger tips pushing across a paper from off which he was brushing some crumbs.

I operated two weeks later, when his physician found himself unable to keep the joint straight, even using a splint. Through a linear cut on the back of the knuckle I sutured the torn end of the tendon to the periosteum of the base of the last joint. The result four years after has been most admirable.

Baseball Finger.—The reverse deformity to the above is now very commonly seen in baseball players. The last joint is violently dislocated backward and can not be replaced, on account of the flexor tendons wrapping themselves round the head of the proximal bone of the joint, which also slips out through a buttonhole of the capsule. This accident makes a permanent bayonet deformity. It is very apt to be compounded by laceration of the skin at the flexure crease. In three such cases I have been able to restore the parts perfectly through incision, though in one I had to resect the head of the bone and make a stiff joint.

Burn Scars.—Some of the worst deformities of the hand one ever sees are produced by burns. These have heretofore been the bête noire of the surgeon. Now it is possible, thanks to Professor Thiersch, to restore many of the worst cases to usefulness by skin grafting.

I will mention only a few of the bad cases I have had.

Two almost similar in deformity were produced in girls working in laundries where ironing mangles were used, the upper cylinder of which is kept hot.

Their hands, being drawn under the roller, were burned to the bone from the knuckles to the wrist, and the resulting slough, including tendons, left a scar which drew the hand directly back upon the wrist.

Dissecting out such massive scars, one brings the fingers as nearly straight as possible and makes Thiersch grafts over the parts exposed. Two such cases are illustrated on the charts.

A unique accident brought a young man to me with broad ulcerated surfaces around each wrist, threatening him with ultimate loss of wrist action. He had been cleaning a pair of gloves with benzene and had on celluloid cuffs. The former ignited and set fire to his cuffs, which burned like tinder. He made frantic efforts to get them off, but they were stiff and

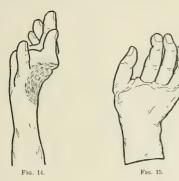

only burned him worse for handling, so that they practically burned themselves off  $in\ situ$ .

I planted Thiersch grafts on both wrists with the happiest result. All scars were perfectly supple six months afterward.

Indeed, I may say that these grafts do not show the contracting tendency that the scar tissue does, and are adapted to burn cicatrices perfectly. Indeed, I have covered the entire arm from the back of the hand to above the elbow with them, and had fine supple skin three years after.

Webbed Fingers.—There is one finger deformity to which this method, therefore, specially applies—namely, webbed fingers. All that is needful is to split the web and dissect out any tough part well down between the fingers, then put a long strip of Thiersch graft up one side and down the other, retaining it by gutta-percha tissue at the flexion.

Such a case of all the fingers I put up in a permanent dressing at the time of operation and removed at three weeks, to find the parts perfectly healed.

Conservative Surgery.—I will not weary you with enumerating further the many hand troubles which always elicit the surgeon's pity as well as skill, but will venture afield into a novel inquiry that has occupied some of my thoughts of late.

Last spring a well-to-do man from the West was sent to me with both hands gone above the wrists. A dynamite cartridge, with which he had been expecting to do some fishing by a method of which the law takes cognizance in some States, had exploded in his hands and amputation had been required. With Western energy he had come East to see if there was not some one who could graft a new hand upon his arm. He said he was sure he could persuade the Territorial Governor to release a convict who would sacrifice a hand for remuneration, which he himself was ready to pay. I could but smile at the Munchausen tale such a deed would make, and took his address, promising, if ever it became possible, I would communicate with him.

Not long after a man came to me from New Jersey who had had a buzz saw plow through his hand from the back, severing all the fingers and the thumb through their metacarpal knuckles, cutting obliquely toward the wrist, and leaving the hand hanging by the skin at the line of the palmar arch. Every tendon—both extensors and flexors, except the flexor of the thumb—was cut across.

It seemed inevitable the parts must be sacrificed, but I de-

cided to see how much could be done, and spent three hours and a half trimming the torn tendons and muscles, resecting the disrupted joints, and suturing the whole. I can hardly believe that the skin and some soft parts alone nourished the fingers, but that one or more of the digital arteries were probably spared, though I did not discover them.

The little finger was the only one that became gangrenous, the thumb and three fingers showing good vitality.

I saw the man a few days since after six months. He now uses his hand for all work, and has a little flexion of the fingers and slight independent flexion of the end joints. The thumb grasps tightly against all the fingers and he writes almost as well as ever.

In view of the fact that surgeons have replaced a finger, an end of a nose, and small parts of flesh under favorable conditions, I asked myself why not a major part, such as a hand or a leg? Is it our inability to nourish the part, or to innervate it, or to unite tendons, muscles, or bone? The latter surely gives no trouble. Tendons are sutured every day, and under favorable circumstances their function is restored. Nerves are frequently sutured and functional restoration is often recorded.

Is it impossible to restore an arterial supply once cut off? Veins are frequently cut and sutured, and perform perfectly afterward. Is there no way to restore an artery?

The question seems to narrow itself down to nourishing a limb in order to restore it.

Experiments.—During the summer I made a few experiments at the Carnegie Laboratory, with the assistance of Dr. Theodore Dunham, and through the kindness of Professor E. K. Dunham.

To see whether a thin glass tube would be tolerated in a sterilized state within an artery, I made a number of half-inch pieces to suit the caliber of a dog's femoral, constricted them very slightly to an hour-glass shape, and smoothed their ends by heat, so that no surface roughness should induce clotting. Cutting the femorals across, I tied each end over the tube by a fine silk thread, and tied the thread ends together. Primary union resulted, and the dog's legs are as good as ever.

I feared, however, that the artery might have become blocked in this case, and the collateral circulation had nourished the limb. I therefore cut one out to see, and tied the femoral above and below. The tube was free in a dilated end of the artery, and slow endarteritis had sealed it below. Whether this would necessarily occur I decided to see by putting a tube in the aorta, where it seems as if collateral circulation could not save the limbs. I chose a cat, whose abdomen I opened and whose aorta I cut across, clamping lightly above and below. Into this I tied an inch of very thin glass tube sterilized by boiling, and filled with water just before inserting into the lower end, so as not to have air emboli. The cat made a perfect recovery, and after four months I show you him to-night, fat and strong, with a glass tube in his aorta.

I afterward tried the same experiment on a large sheep, whose aorta is thicker-walled and larger. Unfortunately, I clamped the aorta so tightly by a broad pedicle clamp that I crushed the inner wall, and at autopsy, two days afterward, the site of clamping was blocked by adhesive clot.

Two days ago Dr. Dunham and Dr. Cushman repeated the experiment on a large dog, and he has thus far been well.

Four months ago I added one step more to the experiments. I dissected out the brachial artery and vein near the axilla of a dog's fore limb, and, holding these apart, amputated the limb through the shoulder muscles and sawed through the bone, leaving the limb attached only by the vessels. I then sutured the bone with a silver wire and the nerves with fine silk. Each muscle I sutured by itself with catgut, making a separate series of continuous suturing of the fascia lata and skin.

The leg was then enveloped in sterilized dressing, a liberal use of iodoform gauze being the essential part. Over all, cotton and a plaster jacket were placed, leaving him three legs to walk on. A small drain of the axilla was removed at the first dressing and a permanent dressing applied, which remained two months. The dog's leg united perfectly, and he is here to show how well he can use it.

Thus we see that, if in an amputated limb an artery can be left, the limb will survive the division of everything else. And, further, it may be asserted that, if an arterial supply can be restored to a completely amputated limb, that limb also may be grafted back to its original or a corresponding stump.

Up to the present I do not feel that we have incontrovertibly proved that arterial continuity can be restored by a glass tube in all cases. But it is not impossible that, if slow proliferating endarteritis shuts up the main artery in a few weeks, the anastomosis through the soft cicatrix of vascular muscle and skin may be able, by the recuperative power of Nature, to take up the nutrition and ultimately carry it on.

The final experiment of the series which I set out to make—namely, the complete amputation of an animal's limb and its restoration—requires preparation, assistance, and time, so that I have not been able to complete it within the period preceding the time appointed to read this paper. I shall therefore report at another date to the Academy such facts as may be further developed.

Some one may ask, Where is the supply of limbs to come from should it ever be possible to graft a leg or an arm? I may say that I doubt not that a limb crushed, let us say, at the thigh or shoulder, requiring amputation, would admit of Esmarch's bandage being applied to expel its blood and of being used after amputation. It should be just as viable as any limb which we keep bloodless for hours under Esmarch's bandage, and have no trouble with when blood is let into it. Why not another man's blood as well as its owner's?

I do not expect that this vision of surgical possibilities will be realized soon, nor do I think enoughhas been proved to warrant much hope, but I feel that experiment in that direction will yield much surgical instruction.

The tolerance of sterilized glass tubes in the larger arteries admits of further application than has been hinted at in this paper.

## Original Communications.

### A CONTRIBUTION TO

THE ARRANGEMENT AND FUNCTIONS OF THE CELLS OF THE CERVICAL SPINAL CORD,

TO WHICH IS APPENDED A NOTE ON CENTRAL CHANGES SECONDARY TO LONG-CONTINUED DISUSE OF AN EXTREMITY.\*

By JOSEPH COLLINS, M. D.,

VISITING PHYSICIAN TO THE HOSPITAL FOR NERVOUS DISEASES; ATTENDING PHYSICIAN TO ST. MARK'S HOSPITAL; INSTRUCTOR IN NERVOUS AND MENTAL DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

WITHIN the past decade the science of medicine has made most remarkable progress. The forward strides during these ten years compare favorably with the progress made in all the fifty years previous. It is in two branches of medicine that we see the manifestations of this advance most clearly-in surgery and in neurology, both, of course, including pathology. Neurology, indeed, has become so perfected that it is rapidly taking a position which will entitle it to rank as one of the divisions of the Æsculapian art most deserving the name of science in its stricter sense. No one can observe the remarkable localizations of lesions in the central nervous system, or the exactness of diagnosis made by logical inference based on accurate knowledge obtained by careful examination, without bearing witness to the truth of these statements. Heretofore that part of the nervous system contained within the skull has claimed the larger portion of the investigator's attention, because the results obtained in this line were often more tangible and More recently, however, work directed toward the accurate localization of the functions of the spinal cord has been done and with encouraging results. Although, perhaps, surgery will never give so extensive and important aid in injury and disease of the spinal cord as it does today in similar conditions of the brain, there is every reason to believe that as progress is made in knowledge of the functions of each segment of the cord, so in proportion will there be an extension of the field of usefulness for surgery in injury and disease of the cord. For instance, if, after an injury which has resulted in fracture of one of the spinal vertebræ or infection that has resulted in abscess of a small portion of the spinal cord, we find that there is a loss of function of certain parts that points unerringly to a certain definite locality in the cord, our best efforts can be intelligently given to remove the materies morbi. But this can be done only when our knowledge concerning the localization of functions is accurate.

The functions of the spinal cord are in the main two in number—viz., reflex action and conduction. The function of automatic action formerly attributed to it can not as such be maintained, the actions that were designated as automatic being simply co-ordinated reflexes purposive in character. These two functions—reflection and conduc-

<sup>\*</sup> An essay for which was awarded the Cash Prize of the Medical Society of the County of New York for the year 1893, embodying work done in Professor Charles L. Dana's neuropathological laboratory at the New York Post-graduate Medical School.

tion-are all-important; but in so far as they assist us in obtaining knowledge of localization, the former is deserving of our best attention, for any given reflex is performed definitely at a certain level and in a certain segment and must have certain cells that are concerned with this function alone, and therefore an effort can be made to localize them precisely. On the other hand, conduction is carried on by the numerous bundles of the white matter. The arrangement of the cells in the spinal cord and the functions and connections of cell groups is still somewhat sub judice. Our knowledge of the white matter, the conducting columns, both as regards their development and functions, is more satisfactory. Information concerning the former is to be obtained by anatomical investigation, by the results of experimentation, and by the observation of pathological changes. The study of each one of these is important, and information obtained by one method should be sustained and corroborated by the others. It is the object of this contribution to assist in demonstrating the functions and groupings of the ganglionic cells in the cervical portion of the cord. The satisfaction of knowing definitely the functions of the cell columns in the spinal cord can not be overestimated. It not only leads to commendable refinement in diagnosis, but it gives a clearer insight to prognosis.

The work has been done in the following way: A study of the spinal cord has been made from both the adult and fætal subject. The information derived from this study, contrasted with and aided by the labors of others who have worked along these lines, is given in regard to the normal grouping of the cells. Then some studies have been made of the cord of the rabbit and the white mouse, and the results from these studies have been used as corroborative evidence concerning the functions of certain groups of cells. Last and most important, the body of the work is taken up with the examination of a spinal cord which presented some striking pathological changes. Some time ago, through Dr. Charles L. Dana's kindness, the opportunity came to me to examine the spinal cord of a young man who had suffered while a child from acute anterior poliomyelitis. Recovery after this disease was complete, except that the right upper extremity remained powerless, stunted, and useless. The history of the case will be considered in detail later on.

The spinal cord is usually described as made up of a number of segments superimposed one upon the other. Each one of these segments corresponds to the exit and entrance of a root nerve. In animals high in the scale of life and in man this segmental nature is not so clearly apparent, but it can be made out. The cervical cord, then, is made up of eight segments, each one of which possesses a certain individuality, and yet is but a single element in a unity. The white columns, externally, are directly continuous from one segment to another. Internally, in the gray matter, are found groups of cells which, appearing in the same relative position throughout many segments, may likewise be said to be continuous from one segment to another. In making a study of the cervical cord from serial sections, it is seen that the shape of the gray matter varies greatly

in the different segments, not only the gray matter of the anterior horns, but also, though to a lesser extent, that of the posterior horns. This variation in shape and outline is due to the varying number of cells at different levels in the gray matter. A glance at the following table, given by Kaiser, shows this clearly:

## Absolute Number of Anterior Horn Cells.

IV.	Cervical segment	28,440
V.	Cervical segment	64,230
VI.	Cervical segment	44,560
VII.	Cervical segment	36,850
VIII.	Cervical segment	47,970
1.	Dorsal segment	27,600
	TD 4 1	240.050
	Total	249,650

Average total of cells from which the brachial plexus takes its origin, 250,000.

Thus it is seen that there is a remarkable difference in the number of anterior horn cells of the fourth and fifth

cervical segments, and we should therefore expect to find a marked difference in the shape of the anterior cornua. A glance at the inclosed outline of the gray matter at the level of the fourth and of the fifth segments (Fig. 1), respectively, will show this difference clearly. At the fourth segment the anterior gray matter is the shape of the thumb -that is, it has nearly the same breadth and configuration throughout except at the extreme anterior, where it tapers somewhat to an apex mesially. At the fifth seg-

ment the gray matter is very much enlarged laterally and is somewhat quadrilateral in shape, its surface area being nearly or quite twice as great as in the segment above. This is not surprising when we keep in mind that the number of cells in the fifth segment is more than twice the number in the fourth.

The cells of the spinal cord, with the exception of the neuroglia cells, are arranged in two ways—the scattered and the grouped. The scattered cells are found in varying numbers throughout the cord. In the cervical region they are more clearly apparent in the lower segments than the upper. The grouped cells are not so distinct in the cervical portion of the cord as they are in either the dorsal or lumbar portion, but still they are grouped with considerable distinctness. The cells of the cervical cord are for the most part large, polygonal, and have many prolongations, the principal one of which, or neuron, becomes continuous with an anterior-root nerve fiber. Here and there

in various sections from different segments are seen large, oval, bipolar cells situated near the junction of the posterior and internal gray matter. These cells in the cervical cord are known as the nucleus of Stilling, while in the dorsal region, where they are extremely prominent, they make up what is known as Clarke's or the posterior vesicular column. Their average size is about 24  $\mu$  wide and 42  $\mu$  long. They receive a certain number of the collaterals (Ramon y Cajal) of the posterior root nerves—that is, lateral branches of the longitudinal fibers of certain columns of the spinal cord (Kölliker), and they terminate in a network forming a delicate felted arrangement encircling the nerve cells. The neuroglia cells consist of elements of the original medullary plates, first appearing as epithelium of the central canal, and are found only in deeper parts of the cord (Turner).

The arrangement or grouping of the motor cells differs in different segments of the cervical cord. It has been customary to refer to the groups of cells in this portion of the cord, according to their position, in a general way, as follows: (1) A mesial group, (2) a latero-ventral group, (3) a latero-dorsal group, and (4) a middle group almost in the center of the anterior horn. From any other than a topographical standpoint such designation and classification is useless.

In the upper cervical region above the exit of the first cervical nerve, where the crossing of the pyramidal bundles is still not entirely completed, there can be seen two groups of cells-one internal toward the column of Türck, the others more external. The internal, if followed upward, becomes the nucleus of the twelfth nerve, and the other becomes the nucleus of the eleventh cranial nerve in the medulla (Kaiser). In addition to these two groups there are scattered cells, principally dorsad to these, and varying in number in different segments. These scattered cells are polygonal, multipolar, and, as a rule, rather smaller than the other cells of the anterior horn. At the level of the upper part of the second cervical segment there can be clearly distinguished: 1. A group ventrad toward the apex of the anterior horn and internal. These cells are moderately large, multipolar, and are possessed of neurons, dendrons, and possibly neuro-dendrons, their neurons being clearly traceable into the anterior nerves. 2. Dorsad to this group and external toward the mixed lateral column, but still anterior, lie a considerable number of cells which are continuous with the external group of cells above mentioned. These cells make up a group known as the accessorius group. This group of cells extends as far as the sixth cervical segment, has nothing in common with the other lateral cells, and is concerned in giving origin to the spinal accessory nerve (Kaiser). 3. At the junction of the middle and posterior horns are many small cells arranged in one or more small groups. 4. Internal to this last group and somewhat more ventrad are seen a varying number of bipolar cells; in many sections they are entirely absent, They are the cells of Stilling's nucleus, the functions of which have before been mentioned. 5. Laterally at the outer border of the gray matter, where the ramification outward of the gray matter occurs to form the reticular substance, lie the small cells making up the group that is by

common consent known as the lateral horn cells of Waldeyer. 6. The few cells at the base of the posterior horns and the scattered cells found in varying numbers between the above-mentioned groups make up the cell arrangement at this level.

The group of cells (1) is remarkable in the persistence of its relative position. In each succeeding segment as we go downward we see it occupying a relatively unchanged position throughout the cord, not alone in the cervical portion, but in the entire cord. In the lower lumbar cord it becomes less marked. Starr, in his article on Localization of the Functions of the Spinal Cord, says: "The group of cells in one segment may be continuous with those in an adjoining segment. No one group, however, can be considered as a continuous column throughout the entire cord." Again he says: "In the anterior horns in which the cells are most numerous a single group rarely extends through more than three segments." With the continuity of this anterior group of cells so strikingly apparent, this statement by Starr is at variance. This group of cells in its position is not in sympathy with the exit of any certain plexus of nerve roots, nor is it limited to any given area corresponding to the origin of innervation of any certain group of muscles such as the respiratory. In the lower animals of the quadruped variety it is particularly well developed, and especially in such as the rabbit and cat, that make use of their dorsal muscles to a great extent. The conclusion would seemingly follow, therefore, that these nerve cells were concerned in giving origin to the nerves innervating the muscles of the back. One is led decidedly to this conclusion not only by the arguments advanced above, but by the consideration that this group of cells is the only conceivable origin of such nerves. It is proposed, therefore, by Kaiser, for the sake of clearness and to avoid confounding this group with other groups in the anterior cornua, to refer to this group as the nucleus for the dorsal or back muscles instead of the medial group. In this article it is proposed to follow that suggestion. Passing to the third segment, the above description of the cell arrangement follows with some modifications. The most important change noticed at this level is the interposition of a small group of very large polygonal cells between the nucleus for the dorsal muscles and the accessorius nucleus. This group, which has been particularly studied by Dees, extends down to the fifth cervical segment. As we pass from the third segment to the fourth and then on to the fifth, examining the sections seriatim, we notice that this group of cells approaches more nearly the periphery anteriorly. After passing the fifth segment the cells are no longer seen as a group. The size of the cell groups and the number of cells making it up differ at different levels and in different segments. The dorsal muscle column remains about the same size throughout the cervical cord with the exception to be noted presently. The accessorius nucleus or column reaches its best development in the third cervical segment. The anterior group is, as has previously been stated, best developed at the fourth cervical segment. At the fourth cervical segment, however, the cell group that strikes us most forcibly on account of its remarkable development in size, and particularly in the number of median cells, is the nucleus for the back muscles. The cells push their way centrally in the gray matter, and at this level are about twice as numerous as in the segment above or below. The group of cells previously spoken of as situated between the accessorious nucleus and the nucleus for the muscles of the back and near the anterior periphery of the gray matter is in all probability the origin of the phrenic nerve. It corresponds in its location exactly to the position to which the phrenic nerve can be traced, and although it is difficult to get experimental evidence corroborative of the functions of this nucleus, there can scarcely be any doubt that its function is as just stated.

As we pass in our study of serial sections from the fourth to the fifth segment, we notice that in the second of these two segments a greater number of cells make their appearance laterally in the gray matter. At first these cells are situated considerably ventrad to where we first saw, and can see even yet, the small lateral-horn cells. To locate them quite accurately we might say that they first appear on a level with the anterior border of the commissura alba if we imagine the commissure extending out laterally in a straight line. At first the cells of this group are few in number and do not attract much attention, but as we pass into the fifth cervical segment a most striking change takes place. The outer lateral margins of the gray matter, which at this level, as has been said previously, is enormously developed, seems to be quite thickly studded with large multipolar cells. As they are carefully studied in different sections made from this level, it will be seen that they arrange themselves with considerable accuracy into three groups. One group is situated anteriorly and near the periphery-that is, at a place corresponding to that stated above as the place where the cells of this group first make their appearance. A second group lies posteriorly some little distance from the periphery, where the gray matter juts out toward the crossed pyramidal tracts. And a third is situated on a level between the two but internally-that is, just dorsad to the center of the anterior gray matter. These groups of cells continue prominently throughout the seventh cervical segment, are clearly marked in the eighth, and begin to lose their striking individuality in the first dorsal segment and terminate at its lowest level. The first group of cells of this lateral nucleus to show signs of disappearance as we go downward in the cord is the anterior, next comes the posterior, and last of all the internal. It will be noticed that this remarkable collection of nerve cells extends from the fourth cervical segment to the bottom of the first dorsal. This, as is well known, is the area from which arise the nerves that enter into the formation of the brachial plexus. That these nerve roots arise from this area has been shown by many anatomists, but by none more clearly than by Krause, who, by the use of a fluid composed of sulphuric acid, glycerin, and water, which corroded and removed the interstitial tissue of the nerves and so left the nerve bundles themselves, traced the bundles to this locality in the spinal cord. Then, again, one of the most important functions of the cell columns of the cervical cord is to furnish origin for the nerves of the

brachial plexus; and if we consider for a moment the functions that have been assigned the other groups of ganglionic cells, we see that these lateral groups of cells are the only ones that can be assigned this important function. In order to avoid confusion and ambiguity in the use of terms, Kaiser has proposed, in the light of our recent knowledge concerning the function of these groups of cells, that the term "upper extremity group" be substituted for the name of lateral group, by which they are commonly known. This suggestion will be followed in this article, for, as will be seen farther on, the results obtained by a study of the pathological changes in the spinal cord of the case, the history of which constitutes the second part of this article, are entirely and strikingly corroborative of Kaiser's statement.

With a word concerning the medial and lateral horn cells found below the fifth cervical segment, we may consider that the foregoing statements embody the knowledge of the ganglionic cells that we are in possession of to-day. The median cells, when we get to the level that has just been mentioned, are situated on a level dorsad to the gray commissure and nearer the middle of the gray matter. These cells are small, relatively few in number, and from this level downward are scattered through the base of the posterior portion of the gray matter. As we pass from the last cervical segment to the first dorsal, and particularly in the lower part of the latter, the conspicuous cells of Clarke's column situated at the base of the posterior root come prominently into view. Taking it for granted that the above represents our knowledge of the grouping of the ganglionic cells in the cervical cord, we will now, by a careful study of the following case, see how far the results obtained are corroborative of the functions that have been imputed to the different cell groups or columns.

A. F., twenty-five years old, born in England, admitted to Bellevue Hospital in the service of Dr. C. L. Dana, October 3, 1893. Family history, so far as could be made out, was negative. When two years old he had an illness which was followed by paralysis of the extremities. The right side was affected more severely than the left. The paralysis gradually passed away, leaving only the right upper extremity affected. As he grew up, all the extremities became large and strong except the right, which remained as it was after the illness. He does not remember that he had any other disease during childhood. He began to drink excessively when very young and had often suffered from the abuse of stimulants. He denies syphilis, but he has had several attacks of gonorrhea and rheumatism. When admitted to the hospital he was apparently suffering from an attack of acute parenchymatous nephritis. Examination of the urine revealed a large amount of albumin with some blood and hyaline and epithelial casts. The heart was dilated and some evidences of pulmonary ædema were beginning to appear. On physical examination, the man was found to be of moderately strong build, and, with the exception of the right upper extremity, he was well developed and muscular. The extremity in question was remarkably undeveloped, normal in form, however, and of about the size of a-child's arm. It was entirely useless. He could not raise the hand or arm or make any shoulder movements whatsoever. Flexion of the forearm in the slightest degree was impossible, as were also supination and pronation. The only movement that it was

possible for him to make with this extremity was very slight flexion and extension of the fingers. That is to say, all the muscles supplied by the brachial plexus below the clavicle on the right side, with the exception in part of the flexor sublimis digitorum and the extensor communis digitorum and their connections in the hand, were paralyzed. The movements brought about by these muscles were only of the slightest and limited kind.

The patient succumbed on November 3, 1892. The autopsy showed an enormously dilated heart, extensive pulmonary ædema, acute parenchymatous nephritis which had been lighted up on an old interstitial degeneration of the kidneys, endocarditis and myocarditis, and a small, hard liver.

The brain and cord were carefully removed, the former being photographed at once and the latter placed in Müller's fluid for a few days preparatory to being examined externally. From a cursory examination made at the time of the autopsy, the brachial plexus seemed to be normal in construction, but the strands and filaments were very small and delicate. The brachial artery was in size proportionate to the arm. After the cord had been in Müller's fluid

for a few days and had become sufficiently hardened to allow of its being handled with impunity, the thece were removed and the cord examined externally. The cord in the cervical region showed an appreciable diminution in outline anteriorly to the right of the anterior median fissure—that is, in the location corresponding to the exit of the anterior root nerves. It is not alone the shrinking in the contour of the cord that is noticeable, but the small size and lessened number of the emerging root fibers. The

most remarkable discrepancy, both in number and size, in the nerve roots is seen at the exit of the fourth, fifth, sixth, seventh, and eighth cervical nerves. In the first dorsal the difference between it and its fellow of the opposite side is not so noticeable, and on examining the dorsal nerves lower down no difference between the nerves of the two sides can be detected. A drawing of the outlines of the cord of the cervical region (Fig. 2) shows the disproportion in the number and size of the nerve roots on the right and left sides. An attempt was made to count the number of strands entering into the roots of the nerves just after they left the cord. Of course it is a difficult matter to be accurate here, as artificial subdivision is so easy. However, great care was taken in the estimate, and the number of strands at the different levels on both sides as they appeared under a magnifying glass is marked on either side of the drawing.

Later on, the completed microscopic examination tended to confirm the statement of Birge, who reached his conclusions after experimentation on monkeys and frogs. Birge found that in each segment of the cord of the frog the number of nerve cells in the anterior cornua corresponded nearly to the number of nerve fibers of the anterior roots arising from these segments. In the case we are considering the number of cells in the anterior gray matter corresponded very closely with the number of fibers in the anterior roots. It is to be remarked also that in this cord the difference in the size of the anterior roots of the right side as compared with those of the left is even more striking than the difference in the number of the fibers.

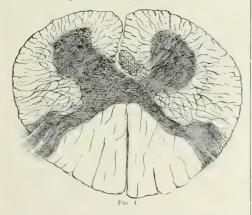

After proper hardening in Müller's fluid, the cervical cord was segmented, and, with the exception of a small portion that was taken from each segment for further hardening in Müller's fluid preparatory to staining with Weigert's hæmatoxylin, the segments were divided into thin pieces and placed for three days in a two-per-cent. watery solution of carminate of sodium. The pieces were then handled in the ordinary way. The small portions reserved for the hæmatoxylin stain were, after remaining for some days longer in the bichromate solution, cut and stained in single sections according to the modified Weigert method—that is, the method without differentiation (See Medical Record, October 10, 1891.) This method of staining was employed merely to determine if there was any medullary degeneration, and also to bring into sharp outline

the shrunken aspect of the anterior cornu on the affected side. This shrinkage is graphically shown in Fig. 3, and is in marked contrast to the outline of the gray matter seen in another disease accompanied by degeneration of the ganglionic cells—viz., progressive muscular atrophy, where the cornua retain their normal size and contour.

The pieces prepared by the carminate of sodium were cut in serial sections, mounted five to a slide, and in all about four hundred were made. It was thought necessary to do this in order that the observer might not be misled by variation in the number of ganglionic cells or differences in cell groups when seen in but a single or a few sections. Frequently single sections made from a perfectly normal cord will vary as regards the number of cells on each side. The drawings then were made from the composite picture, as it were, each drawing representing the conditions existing in five sections cut seriatim. They are not at all diagrammatic, the outlines having been traced by means of the Edinger drawing apparatus and the details filled in from the microscope.

The specimens stained with the Weigert hæmatoxylin do not show any sclerosis or degeneration in the white sub-

stance of the cord—that is to say, the motor tracts, the columns of Türck, and the crossed pyramidal tracts present no change except in size.

Examination of a section of the cord from just below the cervico-medullary junction shows (Fig. 4) that the outlines of the anterior horn on both sides seem to be normal. The crossing of the pyramidal tracts is just being completed. The upward continuation of the anterior motor group of cells is seen internally in both cornua, and this group of cells here is known as the nucleus of the hypoglossal nerve. Externally, on either side, can be seen the accessorius nucleus, and the cells entering into its formation are entirely normal.

(To be continued.)

The Death of Dr. A. Nellis, for many years one of the assistant physicians at the Willard Hospital for the Insane, took place on December 27, 1893, at Geneva, N. Y., of pneumonia. He was graduated from the Albany Medical College in 1872.

## THE EYE TREATMENT OF EPILEPTICS.

A CRITICAL REVIEW OF

CERTAIN FACTORS THAT MAY LEAD TO CONVULSIVE SEIZURES, AND THE TREATMENT OF EPILEPSY WITHOUT DRUGS,

BY AMBROSE L. RANNEY, A. M., M. D.

No sadder misfortune can be fall a human being than to develop epilepsy.  $\,$ 

The horrible aspects of this disease are not confined alone to those who are called upon to witness the attacks, or to administer to the apparent sufferings of the afflicted. Their anxiety and distress are naturally most acute for the few moments during which they see a fellow-being suddenly become unconscious of his surroundings, distorted in face, trunk, and limbs, frothing at the mouth, livid in the countenance, and often bleeding from some wound produced by the sudden fall that ushers in the attack; but to the sufferer from this dreadful malady the distress of mind is not momentary, nor do the alarm and unconquerable dread disappear when the re-establishment of consciousness and physical power follows an attack.

Sooner or later an epileptic must become aware that his attacks are horrible to witness; that they are liable to occur at very unfortunate and unexpected moments; and that it is politic to keep people in ignorance of the existing malady.

For a while such victims are buoyed with a delusive hope that drugs will eventually restore them to health, and for a period varying from a few months to many years they are faithful devotees to some special combination of the bromide salts that their medical adviser or advisers may select. As each attack occurs, or as different physicians are consulted, some slight modifications of the bromide formulæ are commonly made; once again the patient's waning courage and increasing despair are bolstered by words of encouragement and the oft-repeated assurance "that this special combination will probably act better than the last one"; again the patient goes on, too often conscious of a decreasing mental power, a failing memory, or a general bromide stupor, and usually with a disfigured face from bromide eruptions, that advertises his sad malady to the world; again and again his slavedom to drugs is reestablished with professional concurrence, when everything in the clinical history of the patient cries aloud to stop; and during all this time-the years of drugging, mental deterioration, and despair-no attempt has, in most cases, been made or even suggested that sources of reflex irritation of the nerve centers be sought for by methods of scientific precision, and, as far as possible, relieved before the constitution of the patient is broken down by drugs.

This is not an overdrawn picture, nor an exaggeration of the facts, as I see them almost daily in my consultation rooms.

That certain patients can and do take moderate doses of bromides (in all possible combinations) for a time without any very marked injury to health, and often with marked controlling influences upon epileptic seizures, it is useless to deny. Were it not so, the general use of these drugs could not have become so firmly established in medi-

cal therapeuties. The bromide salts (when first introduced to the medical profession) so far exceeded in their results upon epileptic seizures the preparations of zinc, silver, borax, etc., then in vogue, that the enthusiasm of the profession over a possible specific for epilepsy has been dissipated more slowly than it otherwise would have been. It has taken many years to convince most of the leaders of professional thought in this country and in Europe that too much should

Fig. 1 Expression of a patient with a marked hypo-esophoria. The head is tilted, indicative of hyper-

not be expected from the bromide salts; that the beneficial results obtained from them in epilepsy are not permanent, as demonstrated by the frequent attacks that follow a complete cessation of the drug; that the constitutional effects of bromide salts may in chronic cases

of epilepsy prove serious; and that epilepsy is an incurable disease when treated exclusively by drugs, except in the rarest of instances.

The point that I would make in this connection regarding the administration of the bromide salts is, that the principle of treatment of convulsive seizures by drugs is wrong, provided no previous attempts have been made to discover or remove conditions that can be accurately determined and which have been shown, by the observations of more than one, to be related to the causation of epilepsy.

I can see no more intelligence in administering bromides to an epileptic patient until the condition of the eyes, and often of the nose, teeth, genitals, and anus, has been carefully examined for positive sources of reflex nervous disturbance, than I should in administering chloro form regularly to a patient afflicted with a severe toothache to stop the manifestations of an abscess at its root or some exposed nerve cavity.

To benumb the cerebral centers by a drug so that they ceased to respond to reflex irritation from any peripheral source is not curing the disease.

Such a principle of treatment is absurdly irrational and opposed to physiological research. Experiment has clearly demonstrated that epileptic seizures may follow peripheral lesions from the reflex irritation thus excited. This can not to day be denied in the face of overwhelming evidence. To treat epilepsy by drugs without previously searching for all the exciting causes that may exist is no longer creditable to the medical attendant.

On the other hand, while discussing any form of treatment of epilepsy, we are compelled to accept the results of bromide salts upon the number of seizures in any individual case as a basis of comparison, when the results of any other method are subsequently recorded.

Bromide salts (in various combinations) are to-day generally regarded by the medical profession as certainly the most prompt, and possibly for a time the most efficacious form of treatment of epilepsy.

When it can be shown that in any individual case the number of epileptic seizures has been made numerically less than when bromides have been skillfully employed for a sufficient period to test their efficacy, or, in other words, if it can be demonstrated that the condition of any epileptic patient has been improved without the aid of drugs, no medical man

can deny that an important advance has been made in the scientific treatment of this malady.

Fig. 2 — Undateral exophoria closely bordering upon unconquerable diplopia (crossed diplopia)

faith in them as a curative measure in the treatment of epilepsy.

Within the past year I have seen many patients with epilepsy who have been advised by leading medical men of the larger cities to consult an oculist, and it is the exception, so far as I can learn, for medical men of distinction to day to extend to an epileptic patient any hope of permanent cure by medication alone.

Not long since a leading neurologist of this country told a patient afflicted with epilepsy that "bromides, trephining, and eye treatment comprised about all that offered any chance of his improvement."

It is well known that a total cessation of bromides in most instances where they have been administered for any length of time as an aid in controlling epileptic seizures, is followed by a very marked increase in the frequency and severity of the attacks. So marked is the relapse in many cases that the patient, the family, the friends, and even the medical attendant become seriously alarmed, and the drug is again resorted to, in spite of the reasons that led to its cessation, simply as a choice between two evils—mental and physical deterioration on the one hand, and "status epilepticus" or possible death on the other.

One case of this kind comes vividly to my mind in this connection. A young girl afflicted with epilepsy had taken bromide salts for some years with the effect of controlling her attacks to intervals of from ten to fourteen days. She was brought to me for an examination of her case, and very marked defects of the eyes, both of focus and muscular adjustment, were discovered. I advised the friends to discontinue the bromides for a month, during which time I might be able to form some opinion respecting the frequency of her attacks without drugs and have a fair basis for comparison regarding the effects of eye treatment upon her at the expiration of that period. As I proposed to use no drugs during the correction of the eye defect, the condition of the patient could then be contrasted from time to time with her actual condition before the eye treatment, when it was not masked by the influence of drugs.

The parents consented. Within forty-eight hours the child had continuous convulsions for twelve hours, and the medical attendant wrote me that "he was so afraid that she would die that he immediately began the administration of bromides in large doses." He asked me in this case to make an exception to my rule and to allow the patient to take bromides until I deemed it safe to discontinue

them. After two weeks of eye treatment all drugs were discontinued without any serious results to health.

A similar result to this was mentioned in a medical meeting some years ago by a leading neurologist of this city as occurring in one of his patients, whom I advised to discontinue bromides prior to a proposed tenotomy by me upon one of the eye muscles. A condition of continuous epilepsy followed within twenty-four hours — although, while under bromides, the patient had been led to think that a cure was being effected by their use.

In my experience, the cessation of bromides is sure to be followed in almost every case of epilepsy by a very marked increase in the number of seizures; just as a cessation from drinking in a confirmed inebriate discloses to him his actual physical condition. Whether it is wise to continue a habit that is slowly undermining the health,

Fig. 3 Expression of a patient with extreme esophoria; closely bordering upon convergent strabismus, but maintaining binocular vision.

because the victim is afraid to stop, is an important question. Unfortunately, it can not be discussed here. It is imperative, however, in all honest endeavors to determine the results of any scientific procedure, that the results obtained shall not be open to question and invidious criticism from neglect on the part

of the investigator to exclude other factors that may have aided in attaining the published results. In all the cases that I report in this article no drugs were employed while the patient was under my care.

In looking over the records of those cases of epilepsy that have been subjected to the eye treatment exclusively while under my care, I find it impossible to incorporate them all. The number, in the first place, would be too large to admit of their complete histories, and the labor of preparing their records for publication would be too great. Again, many of the patients, for personal reasons, refused to submit to such steps as I deemed wise for their epileptic condition and were dismissed by me as patients, while others had organic diseases that precluded them from being fit subjects for the eye treatment. A certain number had marked evidences of kidney disease, syphilis, and tuber culosis.

Some began treatment, and, after satisfactory progress for a few months, failed to notify me of their change of residence and have not been seen or heard from for a long time. Some have died of intercurrent diseases. A few have been killed by accidents, while ocular anomalies that had not been rectified prior to the accident were being in vestigated.

While it would be of great scientific interest to obtain some deductions regarding the percentages of progress in those patients that have been under this treatment, I am satisfied that a purely numerical basis for estimating results in the treatment of epilepsy is impracticable and misleading.

A patient who (while under bromides) was stupid, apathetic, and incapable of participation in business, has

been greatly benefited (even if his attacks are not markedly less than when under bromides), provided he has regained his normal intellectual status and is capable of self-support.

Numerically, he might be regarded as unimproved if the actual number of his attacks should be counted; but the gratitude of the patient and his friends for his restoration to usefulness is not without reason.

A person who has been enabled to dispense with a constant attendant or nurse has been benefited; a child who can go to school and make satisfactory progress in his classes after escaping the thraldom of bromides is vastly better than a sleepy, sluggish child who has to be con-

stantly cared for—even if he does have an occasional epileptic seiz-

Some years ago, in a reply to a somewhat severe criticism upon the views relating to

Fig. 4. Expression of a patient with an enormous amount of "latent" esophoria.

the treatment of epilepsy that were published in my work on Nervous Discoses,\* I contributed an article to the Boston Medical and Surgical Journal from which I may pertinently quote a few paragraphs. I remark in this connection:

Josh Billings, in one of his characteristic effusions, says:
"I have alwas notised when an individual hain't got the
ability two criticise judiciously, he dams indiskriminately."

Relative to the question of treatment of some of the functional neuroses (such as epilepsy, chorea, neuralgia, insanity, bysteria, headaches, etc.), two distinct and opposed views are now held. Those who still pan their faith upon the internal administration of the various bromide salts in these diseases remain apparently indifferent to the fact (which can hardly be disputed in the face of overwhelming evidence) that serious and permanent harm almost inevitably follows their administration in large doses for any length of time. Those, on the other hand, who argue that scientific methods of precision (when properly employed) will often reveal the existence of an exciting cause for those nervous conditions that drugs only tend to alleviate for a time, and who base this treatment upon the accurate determination of the exciting cause and its complete correction before they resort to drugs, are to day subjected not infrequently to ridicule and personal attack by others not thoroughly posted in the methods employed by them.

It took Lister and his followers some ten years to teach the protession that, if the antiseptic method was to be tested as a basis for adverse criticism or for the benefit of suffering humanity, the operator must clean his finger nails; that he must also wash his hands with great care, make his knives aseptic, and follow out the published plan of procedure with due regard to detail, before the results obtained could be worthy of publication or in any way reliable as a basis of scientific deduction.

Not long ago a famous orator told the following fable:

"A well-red horse who, in his greed, scattered grain upon the floor of his stall, became in consequence the constant companion of a rooster who picked up the scattered outs. One day the rooster suggested that friendly relations were desirable and

<sup>\*</sup> Lectures on Nervous Discusses. F. A. Davis, Philadelphia, 1890.

would be put on a much firmer basis by the existence of a solenn agreement between them. The horse assented, and, on asking the basis of the compact, was told that it should read: "Neither qi'us shall step on the other's freek."

I do not desire to carry out in full what, to my mind, might be the true application of this fable. None of us desire to stir up discord if important facts can be insured, a fair hearing without recourse to asperity—but the establishment of a great truth can not be crushed by being "stepped upon."

I quote again, in this connection, from a later brochure of mine the following paragraphs:

"One thing is evident—viz., the view that 'eye-strain' can and frequently does cause serious nervous conditions must be either true or false.

"If it be false, then it has made steady progress in spite of its weakness and against organized and bitter opposition; if false, then the growing list of converted advocates among the younger oculists and neurologists is incapable of explanation; if false, then the thousands of suffering humanity are deceived who believe that they have cause for the deepest gratitude in the recognition and relief of an existing 'eye-strain.' It is contrary to all precedent that a mere 'fad' should steadily flourish and gain strength year by year over a period of many years; neither does the statement that some cases have failed to be benefited by this treatment have any weight in argument. Every method of treatment of disease sometimes fails to relieve individual cases; yet no one attempts to discard all therapeutical efforts in consequence of this fact, because such a deduction would be manifestly illogical."

In the reported cases that follow, some terms are employed that may require explanation to the general practitioner, although they would be easily understood by the oculist. These are comprised in the following table:

Terms related to the focus of the eye (refractive terms). Hypermetropia (fur-sightedness). A shallow eye (from the front to the back), causing an imperfect focus of objects. Myopia (near-sightedness). An chargeted eye (from the front to the back), causing an imperfect focus of objects.

Astromatism. An irregularly curred cornea or lens, causing distortion of images on the retina.

EMMETROPIA. A perfectly constructed eye. Esophoria. A tendency of one or both eyes to deviate toward the nose.

Exophoria. A tendency of one or both eyes to deviate toward the temple.

HYPERPHORIA. A tendency of one eye to rise above the level of its fellow.

ORTHOPHORIA. Normal adjustment of the eye muscles.

HETEROPHORIA. A term that covers all forms of abnormal muscular adjust.

Adduction. The power of the internal muscles of the eyeballs. It varies in health between 25 and 60°.

Abduction. The power of the external muscles of the eyeballs. It should be 8° in health.

Sursumduction. The power of the vertical muscles of the eyeballs. The right and left should be alike. Various forms of glasses employed by oculists. Spherical. Ground upon a convex or concare sphere. Used to correct hypermetropia and myopia.

Cylindrical, Ground upon a convex or concave cylinder. Used to correct astigmatism.

PRISMATIC.—Two plane surfaces of glass meeting at an angle. The thick side is termed the base of the prism. Used to relieve errors of adjustment of the eve muscles.

Before I pass to the consideration of individual cases of epilepsy whose histories have been prepared by me with some care (not alone with the object of showing the ultimate results of treatment of the eyes, but also of demonstrating that permanent and beneficial effects have been secured in correcting anomalies of adjustment of the eyes by graduated tenotomies upon the eye muscles) it may be well for me to impress upon the reader an important fact which seems peculiarly hard for some oculists to grasp—viz., that "latent" anomalies of the eye muscles are to-day as well proved as is the existence of "latent" hypermetropia.

By this I mean that the amount of esophoria, exophoria, or hyperphoria discovered at the first examination of any patient does not necessarily represent the actual amount that exists. In many cases it constitutes but a very small proportion of the amount that has to be corrected before beneficial results are to be expected from eye treatment (see Cases IV, VI, VII, XIII, XIII, and others).

I recall an epileptic who manifested for many visits at my office but one degree of esophoria; yet that patient eventually disclosed, after weeks of careful observation, a

high degree of esophoria, and at times had unconquerable double images (homonymous diplopia).

My friend Dr. G. T. Stevens has very happily illustrated this very important point in a paper upon Heterophoria,\* read by him before the Pan-

Fig. 5.: Extreme manifest hyperphoria, with some cophoria datents. The tilting of the head (that often accompanies hyperphoria) is quite marked.

American Medical Congress. I take the liberty of quoting a few paragraphs that bear vitally upon the investigation and solution of complex ocular problems. He says:

"One of the first of the elements in the management of these cases is patience. The oculist who imagines that he can measure and correct his cases of heterophoria in an offhand manner has not reached an understanding of the first principles of the subject. A case which at first appears quite simple and easy to handle may prove to be one which for its best correction may demand the exercise of great skill and of unwearied patience during many months.

"We can not know when we begin the treatment of a case of heterophoria the full meaning of the indications which we then discover. One who thinks that he has found an instrument which will reveal latent heterophoria is surely laboring under a misapprehension. As we go on in the treatment of these cases new difficulties may arise and new efforts may be

\* N. Y. Med. Jour., Nov. 18, 1893.

Terms related to the muscles which move the eyes (muscular terms). demanded. This is no reason for not beginning the work, and less for abandoning it before completion.

"I have sometimes illustrated these progressive difficulties by recalling the experience of one who climbs a mountain. He sees before him a height which appears to him the summit which is to reward him for his effort, but when he reaches it he sees before him another even higher than the one which he has surmounted. He ascends higher, and when at length he attains to the second height the real summit is still above him. Is he therefore to say, 'There is no end to this, and one might climb ind-ficitely without finding the summit?'

"There is a summit, and one may reach it if he has the needful strength and courage.

"I am sometimes asked by my colleagues if there is no end to the treatment of these cases. Does not the condition which has been apparently removed return? Must the treatment not continue indefinitely?

"The heterophoric condition which has been in any measure properly corrected does not return, but that part of the original defect which was at one time latent may at a subsequent time become manifest.

"There is as surely a limit to this work as there is a final summit to the mountain, and when one reaches that limit he has an infinitely greater satisfaction than he who finally gazes upon the stretch of bills and plains and lakes from the elevation which he has earned.

"Many who do not care to take the trouble to climb decline to accept the reports of those who do, and many an eminent man who has lingered about the foothills of this work is incredulous because he can not obtain the same grand view that has been described by some one who has gone beyond.

"An essential to success in this work must be a thorough knowledge of the principles governing the tensions of the muscles with which we work.

"Instruments can not know these principles. They are only to be learned by long and patient research on the part of the oculist."

Again, I would endeavor to disabuse the professional mind of an impression that seems to be too common, in spite of the amount of literature that has appeared during the past decade upon this field. The development of "latent" muscular anomalies of the orbit is not to be conjounded

Fig. 6 Expression (1 a patient with a high degree of manifest esophoria and a moderate degree of hyperphoria datent. The head is slightly tilted—a posture that is suggestive of existing hyperphoria.

with the effects produced by forcing the ocular muscles to adjust themselves to prismatic glasses that are not properly prescribed.

There is a radical difference between "forcing a patient to adjust his eyes to a prismatic glass" that he has had given him and assisting a patient in his ocular perplexities by giving him a prismatic glass that only partially corrects the

amount of heterophoria that he discloses.

So long as any patient accepts a prism for the relief of an existing eye-strain that he discloses and still shows (while wearing it) a clear surplus that the prism fails to correct, we are simply following the guide that the patient unconsciously gives us as a step toward the solution of the problem without any possibility of "forcing the patient to adjust for the prism." Again, if we find (by measuring the strength of the individual eye muscles) that the amount of deficient power in any one set of muscles corresponds to and justifies the amount of abnormal deviating tendency of the eyes that the patient discloses, we are still further strengthened in our position relative to the prismatic glass prescribed.

Case VI illustrates this point as well as any case can; and the reader is referred to the history of this patient and the details of his treatment. This boy had almost absolutely perfect refraction, even under atropine; so that all question regarding his "apparent muscular anomalies being caused by some error of refraction" is refuted in this case.

Moreover, his heterophoria was extreme but almost totally "latent." The deviating tendencies of the eyes were both vertical and lateral—"hypo-esophoria."

Even to-day (five years after the first examination) some esophoria still remains uncorrected except by a prism, although vertical equilibrium seems to be fully established. The only fit the patient has had in over two years followed the discarding of the esophoria prisms, and he has had no attack since they were ordered to be worn constantly.

This boy's history has been published by me before, as one of the most remarkable cases on record. I am glad to report that during five years from the date of his first visit to my office he has had but six days during which seizures have occurred, in spite of the complete withdrawal of all drugs, and that he has passed two years and three months without a seizure, when, by eaving off his prisms contrary to instructions, he had an attack after going a few days without them, but has had none since the prismatic glasses have been resumed.

I expect soon to relieve the remaining esophoria by a tenotomy, and to dispense with all glasses by so doing. I have been slow in doing so, because I desired that the patient should become thoroughly accustomed to the altered ocular conditions that followed four graduated tenotomies in a comparatively short time, and that ample time should be afforded him to disclose any latent heterophoria that might remain.

Now, what has been done for this boy thus far by "eye treatment"? He has already passed over five years without recourse to poisonous drugs; he has been saved thus far from a life in a lunatic asylum and restored to usefulness and health; he has had, except on six occasions, complete immunity from his horrible disease in spite of the total cessation of bromides he has returned to his former association with his companions; and he is to-day able to go about without an attendant, or the dread of impending disaster and possible confinement.

He has happily learned, I trust, that excessive and violent exercise and a disregard of instructions about wearing his glasses are dangerous to his comfort, as they tend to cause an epileptic attack, and also to derange his digestive apparatus seriously. Had it not been for such extreme imprudence, he would probably have been entirely free from attacks during the past three years.

Do we know that this remarkable change is due to the eye treatment? Most certainly!

This patient had never before passed so long a time without attacks as he has since eye treatment was begun, although he had been constantly drugged, according to the most approved fashion of the present day, for his epileptic seizures. During the year preceding eye treatment he had had thirty-four days in which a series of fits occurred, although heavily drugged

with chloral and bromides. He had found in the bromides for some years the only refuge that medicine offered to keep these frightful attacks within bounds that did not seriously endanger life. He naturally felt, as did his parents, that to let go that anchor was to drift beyond aid into hopeless despair. When, therefore, I stopped his bromides at the first visit, every one concerned (the patient, his parents, his friends, and myselt) felt quite sure that, unless something was done as a substitute for the drugs, the fits would surely become more frequent and severe. This substitute for drugs took the form of an operation for what I deemed the exciting cause of the attacks. Another operation was done on the corresponding muscle of the opposed eye, as soon as the necessity for it became apparent. Then we felt comparatively safe, and the patient could await with greater safety the effects of prismatic glasses.

When a house has been partially burned no one expects that putting out the fire will at once restore the house. It does, however, prevent further damage, and decreases the time and cost demanded for its restoration. Hence it is always deemed imperative to extinguish the fire without unnecessary delay.

We must all admit, I think, that epilepsy is certainly the gravest of all the functional nervous maladies, and that it is, as a rule, incurable by drugs; hence, as I have remarked in a previous discussion concerning this subject, "one radical cure of epilepsy without the aid of drugs offsets a thousand failures as a scientific proof of a discovery."

Case I again illustrates the fact that a latent esophoria (independent of any marked error of refraction) was clearly a factor in producing from two to ten attacks of petit mal during each day, which bromides failed to control. He has passed nearly a year without any symptom of epilepsy since the date when the

esophoria was radically relieved by graduated tenotomies.

Case II shows clearly that hypo-esophoria
was a more important
factor in causing epilepsy
than astigmatism. No
marked relief followed
the correction of the latter by glasses; but a remarkable change for the

Fig. 7 Expression of a patient with "latent" hypo-esophoria. The tilting of the head dudleative of hyperphoria is marked.

better followed graduated tenotomies upon the interni and the superior rectus muscle.

Case III illustrates a very remarkable improvement in an epileptic idiot that followed the correction of double convergent strabismus by two tenotomies and a high degree of latent hypermetropia by glasses.

Case IV illustrates a complete cure of chronic epilepsy (that had withstood all therapeutical treatment for twenty-four years) through the correction of latent esophoria by graduated tenotomies and latent hypermetropia by glasses. For seven years, without drugs, no epileptic seizures have occurred.

Case V shows the existence of an extreme degree of astigmatism in one eye, associated with a large amount of latent esophoria. The patient has regained his full mental power (that became seriously impaired by the use of bromides), and has only had one slight epileptic seizure in three years following graduated tenotomies upon both interni and a full correction of the astigmatism by glasses.

Case VI has already been discussed at some length. Only one slight seizure has occurred in three years, as contrasted with thirty-four days of almost continuous convulsions during the year preceding the eye treatment, while the patient was heavily drugged with bromides and chloral.

Case VII illustrates the fact that an epileptic patient, whose family history was not of a promising kind and who had inherited a marked tendency toward nervous disease, was cured through the relief of latent esophoria by graduated tenotomies, and the correction of a moderate degree of latent hypermetro pia by the use of glasses for reading and other eye work at close points. No epileptic seizure has occurred for two years and six months. The direct relationship between the eyes of this patient and his epileptic seizures was shown (somewhat unusually) by a very marked tendency toward an epileptic attack whenever an attempt to measure the strength of the interni was made prior to the dates of the graduated tenotomies for the relief of the esophoria.

Case VIII illustrates simply that admirable results from graduated tenotomies can be obtained in cases of extreme heterophoria. This patient unfortunately lacked sufficient patience and fidelity to enable me to determine the ultimate effects of the eye treatment upon his epileptic seizures.

Case IX shows that a sudden withdrawal of bromides from the patient prior to the correction of the heterophoria caused (within twenty-four hours) a state of continuous epilepsy that imperiled life, and that, after two graduated tenotomies, the bromides were suddenly withdrawn from the same patient without any ill effects. She has fewer attacks to-day than when under the influence of bromides, and is markedly improved in her general physical condition. Photographs of this patient in my possession, made at intervals from untouched negatives prior to and during the eye treatment, illustrate the physical change in a remarkable way.

Case X proved to be one of extreme latent esophoria. Although the power of abduction has twice been apparently brought to nearly the normal point by graduated tenotomies upon the interni, a gradual diminution of the power of the externi has occurred. The patient has been very markedly benefited, however, by the eye treatment.

Case XI was one of severe and frequent epileptic seizures that, unfortunately, was terminated by the accidental death of the patient before the final results of eye treatment were determined. Sufficient improvement had, however, been observed to justify the belief that still better results would in time have been recorded. The "family history" in this case was a bad one, and the patient was a difficult one to control, being headstrong and disobedient to instructions.

Case XII illustrates a remarkable restoration to health (after a complete withdrawal of bromides from a patient that manifested their poisonous effects to a marked degree) from the correction of eye defects that were indirectly creating reflex nervous disturbances. Not only have all epileptic seizures ceased for the past three months, but all hysterical attacks, that were formerly so frequent, have apparently been entirely exact.

A letter, dated November 25, 1893, written by her husband from the West, says:

"I am glad to say that Mrs. G. passed through the trip sately, with no trouble of any kind. She did not even have a headache, nor feel in the least nauseated, which is something unheard of for her before. She appears bright and cheerful, and we feel that we owe it to you."

Case XIII is one of the most interesting cases, from a scientific standpoint, that I have yet encountered. Under full effects of atropine, she showed no errors of refraction, and for several successive days no apparent error of adjustment of the eyes was manifested. The case looked unpromising, and the cause of her epilepsy seemed to be involved in obscurity. For a week the effects of esophoria prisms upon the patient were observed, a low abducting power being the only guide to the existing

latent heterophoria that eventually was disclosed by the patient. A radical correction of the heterophoria (that was totally latent) by one graduated tenotomy has for over nine months arrested any tendency to convulsive seizures, and apparently effected a complete restoration to health in many other ways.

(To be continued.)

# THE RELATION OF NEOPLASMS TO NORMAL STRUCTURE.

By THOMAS O. SUMMERS, M. A., M. D., r. s. sc. lond , the , warkesha, wis.

Too little attention has been paid by pathologists to the precise morphological relation, which exists always as a constant factor in the problem of abnormal structural development, between what may be called the dynamic equivalent of growth in a neoplasm and that of the normal physiological structure. At first blush this may smack a little of the transcendental or metaphysical—too much, perhaps, to command the attention of "the busy practitioner"—but a little further investigation will show that there is an immense practical significance behind this nebulosity of sesquipedalic nomenclature, and it is this which I propose to lift away as far as the limits of a journal article will allow

When the great pathologist Virchow, whose work on cellular pathology was for a long time the gospel of medical literature, at last came to the conclusion that all of his beautiful cellular system was founded upon untenable premises, and was constrained to reconstruct his whole pathological philosophy, it was then that the first clear light was thrown upon the mode of development of morbific growths, which were hitherto recognized as distinct cellular growths, independent of the structure in which they were found, except so far as the elements of nutrition were concerned, which furnished the pabulum for their development. In defining the varieties of malignant growths, therefore, it was natural, after determining the specific character of cell which entered into its morphology, to stop short at this point without looking deeper into the origin of such cellular activity to determine the exact morphological relation of the pathological structure to that in which it was found imbedded. Later investigations proved, first, a constant relation between certain tissues and the neoplasms possible to their cellular structure. For example, the numerous varieties of cancer were found to be possible only to those tissues whose cellular structure presented the same cellular organon, or plan of proliferation, as well as morphological similitude itself.

While it was beyond question that the neoplasms or morbific growths found in muscular tissue were never to be found in bone, for example, and while it was well known that the cell of any morbific growth, laid side by side with the cell of the normal physiological structure in which it was constantly found, presented the same general morphological characteristics, both in appearance and in development, it was remarkable indeed that this constant likeness was not given the practical importance which was due to

it-the study of the growth and the remedial measures considered for its removal or arrest, proceeding upon the basis of its absolute independence. Where is to be found a stranger or a graver error in the whole realm of pathological investigation? What, then, are we justified in establishing as a constant relationship between the two? is the practical question which lies before us -the answer to which not only determines the law of pathological cell development, but opens up to us the proper line of therapeutic attack, which has been so uncertain and obscure. The line of demarcation which divides the pathological from the physiological is often so very vague that it is only in the fully-formed structure that we find the differentia of development. We must therefore start out with this formula, which, from the inductive fact that it has never been contradicted in pathology, amounts almost to an axiom. Every cell which enters into the structure of any abnormal growth presents a like morphological character with the cell of the normal structure in which it is found. The next proposition, which is the natural corollary of this formula, is that the mode of development of any neoplasm or morbific growth has the same general line of activity, and however different in ultimate appearance may be this growth from the structure in which it is imbedded, the plan of nutritive evolution is the same for both. It is, then, clear that the nearer we bring the cellular character of the neoplasm to that of the normal structure upon which it has been pathologically superinduced, the greater similitude will there be in the result of the development. Does not this, then, suggest to us naturally that the true line of therapeutic action lies in the direction of reducing the nutritive conditions of development in the morbific growth, as far as possible, to those which govern the structure in which it is developed-which is indeed, as it were, the physiological matrix of the neoplasm? Were it possible for us to divert the selective nutritive material which is common to both the physiological and pathological structures in such close proximity of growth into the normal channels of the organism, and by this means arrest the pathological growth before its developmental differentiation is fully established, we should thus, by the substitution of a hypertrophic condition of the physiological structure, change a neoplasm into a hyperplasm, whose ultimate differential of tissue would be so reduced as to nullify or sufficiently minify the destructive effects of the neoplasm upon its local surroundings and upon the organism at large, for it is in the divergence of development that the danger lies. This fact has been practically recognized in the classification of tumors as malignant and benignant—the former, from a structural standpoint, being those whose rapidity of growth in a divergent line of development has reached that point or degree of dissociation with the subjacent or circumjacent tissues which makes it no longer possible for both to draw upon the nutritive supply without destructive assimilation. the latter being those which preserve, as it were, the parallelism of growth within the limits of retrograde metamorphosis.

This may look like putting the salt on the bird's tail to

catch him; but closer inspection will reveal the fact that it is possible to divert the neoplastic pabulum into physiological channels by the digestion of those pathological structural elements through the medium of some agent that by elective affinity may separate these from the cells themselves without attacking the physiological structure. It is well known to pathologists that the great distinguishing characteristic of morbific growths is their instability, their tendency to degeneration or retrograde metamorphosis as compared with normal tissue. Indeed, it is this degenerative tendency to which their malignity is chiefly due, and in proportion to the degree to which this prevails does the malignant effect upon normal tissues become apparent, for in the physical as in the moral world the facilis descensus Averni prevails-contiguity of growth and similitude of developmental organon rendering it easier for the normal tissue to take on the pathological tendency of the neoplasm than for the latter to rectify itself into normal physiological lines of development. It is just here that we must come to the rescue, and this may often be accomplished in the early stages of the pathological growth, not by direct destruction, but, on the contrary, by the excitement of nutritive activity in all the surrounding parts. But the question will be asked, and naturally enough, Does not this supply of excessive pabulum furnish material for the increment of growths in the pathological structure as well as in the subjacent physiological structure? Undoubtedly it does. But while we may increase the ceilular activity of the growth thereby, we are at the same time increasing the vital resistance of the normal tissue and holding in abeyance the retrograde metamorphosis of the neoplasm to which the destructive assimilation of the normal structure is due. And, further, it will be seen to follow that this parallelism of growth to which we have referred is thus maintained, holding a malignant tumor in this way within the destructive limits. Let us advance one step further in our reasoning and it will be at once apparent that if at the same time that we increase the pabulum upon which the growth of both the normal and abnormal tissues draw for support we should bring into play some such agent as that referred to above, which would, by an elective process, attack the stroma of the neoplasm, which is weaker than the "formed material" of the physiological structure, we shall come very near fulfilling those conditions which will cause an atrophy of the neoplasm, even if we have a hypertrophy of the normal structure as a permanent result. In another paper, purely practical in its character, I have suggested pepsin as a therapeutic agent in pathological conditions which have been established in accordance with the laws of neoplastic growth which I have here endeavored to elucidate. Suffice it to say in this connection that it is the only agent known to modern therapeutics which possesses this elective affinity to such an extent as to digest products of retrograde metamorphosis in the presence of normal tissue without arresting or destroying the cell activity of such tissue. It will-as I have often proved, where the vital resistance or, to speak with greater scientific accuracy, the dynamical equivalent of the growth force is very weak-carry its dialytic action into the very

cell itself of the neoplasm without injury to the tissue in which it is imbedded.

From what has been said, therefore, I think it is clear that I can substantiate these conclusions:

- 1. The morphology of a neoplasm always presents a similitude of cell characteristics with the normal physiological tissue in which it is imbedded.
- 2. The *organon* of development is in the same line of cellular activity at first, and the extent of divergence from that line determines the degree of malignity.
- 3. Parallelism of growth holds the neoplasm within the bounds of retrograde metamorphosis upon which destructive assimilation of normal tissue depends.
- 4. Parallelism of growth may be maintained by an increment of pabulum for both physiological and pathological structures lying adjacent to each other.
- 5. Any agent that by elective affinity will attack the stroma of the neoplasm without affecting the formed material of the physiological structure will tend to cause or will cause an atrophy of the neoplasm and a permanent hypertrophy of the normal tissue and neutralize the effect of the destructive assimilation of the abnormal growth upon the normal structure in which it is imbedded.
- 6. There is no known agent but pepsin that fulfills this indication with any degree of satisfaction.

In another paper I shall endeavor to show the practical means at our command of establishing this parallelism of growth force, and also the manner of applying pepsin as a therapeutic agent in the arrest and destruction of neoplasms.

The Columbian Dispensary, of Brooklyn.—A new charitable undertaking has been begun at No. 140 Clermont Avenue, Brooklyn, in a dense population poorly provided as to medical attendance. Dr. George R. Kuhn is the leader in the attempt, but he has the support of the clergy in his vicinity. The following physicians will give their assistance to the dispensary: Dr. D. E. Callaghan, Dr. A. F. Carroll, Dr. P. J. Curran, and Dr. James F. Gallagher. It is designed to make the institution strictly unsectarian.

The Death of Dr. Joseph John Summerell, of Salisbury, North Carolina, removes the superintendent of health of Rowan County and one of the ex-presidents of the State Medical Society. He was a graduate in arts of his State's university, and in medicine of the University of Peunsylvania, in the class of 1844. For six years he was a member of the State Board of Medical Examiners, and for two years was chairman of the County Court. He was a corresponding member of the Gynacological Society of Boston. The Bulletin of the State Board of Health expresses its feeling of loss in his decease in the following terms: "At the age of seventy-four, this faithful physician, sterling citizen, and Christian gentleman, surrounded by his children and in possession of the respect and affection of his neighbors, after a long life of usefulness and honor, passed to his reward. The State, the medical profession, and especially the cause of sanitation in North Carolina, have suffered a serious loss. While the oldest, he was, nevertheless, one of the most active and enterprising superintendents in the State. We shall miss him, personally as well as officially." The cause of his death was double pneumonia consequent upon an attack of epidemic influenza.

THE

# NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by FRANK P. FOSTER, M. D

NEW YORK, SATURDAY, JANUARY 13, 1894.

THE STATUS OF ACTING MEDICAL OFFICERS OF THE  $$\operatorname{ARMY}$.$ 

About two years ago Dr. John T. Nagle, of New York, sought by application to the Secretary of War to be awarded one of the medals of honor authorized by Congress in 1863 to be presented to such officers, non-commissioned officers, and privates as had most distinguished themselves in action. His request was denied, partly on the ground that he had allowed so long a period as twenty-eight years to elapse before making it and partly because the acts of gallantry for which he sought recognition had not been mentioned in official reports, but chiefly for the reason that at the time of performing those acts he was neither officer, non-commissioned officer, nor private. In a renewal of his request, made last summer, Dr. Nagle states that the conspicuous acts of bravery on which he founds it were performed by him at the battle of Kernstown, in Virginia, on July 24, 1864, while he was serving as an acting assistant surgeon, or "contract surgeon." It seems that the commander of a body of dismounted cavalry was wounded and disabled, and its other commissioned officers abandoned it, whereupon Dr. Nagle assumed the command and rallied the men; that he attempted to spike a gun in the face of the enemy and assisted in saving it from falling into the enemy's hands when it had been abandoned by the Union forces that he set fire to a baggage-wagon and destroyed other material of warfare that would otherwise have been captured; and that he was one of a party of five that rode under a flag of truce toward the enemy's lines at Bolivar Heights and reported the disappearance of the enemy to General Sigel, thereby relieving the besieged army at Maryland Heights and liberating it for action. Dr. Nagle is quite warranted in adding, as he does, that these acts, baving been performed while he was serving as a medical officer, ought to be considered more meritorious than if they had been done by a field or line officer in the line of duty. Testimony as to the performance of the acts specified is borne by Lieutenant-Colonel Young, now of the 4th Cavalry, and by Captain Mason, of the 2d New York Cavalry.

Dr. Nagle has recently published a pamphlet in which he recounts the facts pertaining to his petition and to its denial by the War Department, and argues very forcibly against the justice of that denial. His argument deals principally with the ruling that an acting medical officer is not an officer within the meaning of the act. This ruling rested partly on the statement that acting medical officers were not required to wear a uniform. We [have heretofore supposed that this was the case; the writer of this article, who himself served as an acting as-

sistant surgeon for several months, never saw such a medical officer in a first lieutenant's uniform, although he distinctly remembers that the medical officer of the day always wore a sash and, in the absence of a commissioned officer, actually exercised command over the non-commissioned officers and enlisted men at a post. Dr. Nagle, however, adduces the testimony of many gentlemen who formerly served as acting medical officers, to the effect that they were required to wear the uniform; furthermore, he cites a number of official documents in which such persons are spoken of as medical officers. All things considered, it seems to us that he has made out a case strong enough to call for further consideration on the part of the War Department, and we hope that his petition will eventually be granted, and on the ground that an acting medical officer is really an officer.

## MINOR PARAGRAPHS.

#### THE ADIRONDACK SANITARIUM,

WE have received the report of Dr. E. L. Trudeau, of the Cottage Sanitarium at Saranac Lake. This is the ninth annual report, and is for the year ending November 1, 1893. The friends of this enterprise have been liberal despite the hard times, and two gentlemen whose names are not given have come forward with a donation in the form of "a five-year laboratory and research fund instituted for the purpose of defraying the laboratory expenses incurred in the study of the specific treatment of tuberculosis, and to meet the expenditure incident to any original researches on this disease undertaken at the sanitarium." This is believed to be the first fund of the kind established in this country. A donation has also been received to build a wing-in memoriam-for the purposes of a library and writing room. The number of admissions in 1893 was a hundred and fifty-six, of which eighty-eight is the number reported on for the year. There were twenty-seven patients treated with modified tuberculin. Thirteen had been discharged, three had been cured, in three the disease had been arrested, two had been improved, and five were unimproved. There was no death. Free treatments for needy patients amounted to a total of three thousand nine hundred and thirty days.

## THE INFLUENCE OF ULTRA-VIOLET RAYS ON SMALL-POX.

According to the Universal Medical Journal for December, the method of treating small-pox as recommended by Finsen has been successfully employed by Lindholm, of Bergen. The patients were placed in a room from which the ultra-violet rays of light were shut out by red window panes or by covering the windows with red curtains. Twenty cases, of which ten were in unvaccinated children, were treated in this manner with complete success; all the patients recovered, although severely attacked. The reuption dried up shortly after its appearance, there was no fever of maturation, and the patients recovered soon and with but few scars.

## A LARGE INFECTIOUS HOSPITAL PLANT,

London has been suffering from an epidemic of scarlet fever, and the existing hospital accommodations have been found wholly inadequate. The total number of beds at the command of the Metropolitan Asylums Board has been 3,300, whereas not fewer than 5,000 beds are needed. Authority having been

obtained by the board, it has purchased land, at a cost of \$60,000, thirty-three acres in all. Twenty-three acres have been selected for a permanent structure soon to be begun; ten acres will be used during the present emergency for the purposes of temporary buildings large enough to hold 400 beds. This temporary hospital will cost \$300,000, and will be almost wholly needed for the scarlatina patients that are sent to hospital from the southwestern parts of London. The cost of maintenance is stated at \$50,000 per annum. There will be ninety nurses and assistant nurses. There will be sixteen pavilions, used as wards, each to contain twenty-four beds. The air-space for each bed will be 2,000 cubic feet.

## A RICH GIFT TO THE NEWBERRY LIBRARY.

Du. Nicholas Senn, of Chicago, has given his collection of books to the Newberry Library, of Chicago. It is estimated that \$50,000 could not duplicate this collection. It is especially rich in works on surgery, containing, as it does, the collection made by Dr. William Baum, the professor of surgery in the University of Göttingen. This latter library, bought in its entirety by Dr. Senn, when it reached Milwaukee, came to its new owner packed in fifty-two cases, making an entire car-load. The Journal of the American Medical Association for December 30th gives us these data, and also states that Mrs. Senn is the prime mover in this action. Knowing the great worth of the collection, and appreciating the almost daily danger that a private residence has of loss by fire or other casualties, she has prompted the professor to put the books in a safe place at all hazards. He weighed the matter carefully and concluded to give his books to the Newberry Library, and thereby place them at the disposal of his medical brethren.

## THE INSANE OF KINGS COUNTY.

The new Board of Charities of Kings County has adopted a resolution looking to the transfer of the lands and their charge to the State's care. If this step is taken, it will result in the saving of fully \$160,000 per annum to the taxpayers, for so long as the lunatics remain as they are there is a double tax to pay, and this is quite contrary to the temper of the times. Action by the Legislature, now in session, will be sought for in order to get remuneration for the costly buildings that must be disposed of in some way if the transfer is to be made.

#### CAISSON DISEASE.

FOUR cases of this affection have occurred within the past month, three of which have ended in recovery, in connection with the work on the gas-tunnel under the East River. It is stated that there have been seven fatal cases since the beginning of the work, about twenty months ago.

#### ITEMS, ETC.

The Philadelphia Polyclinic has arranged to give a week upon the diseases of the heart and lungs, beginning on the 22d inst., the instruction being arranged on a plan similar to that pursued in the recent week devoted to cataract.

The Hoagland Laboratory, Brooklyn.—Dr. E. H. Wilson has been appointed director of the department of bacteriology, in the place of Dr. Sternberg, who resigned on taking office as surgeon general of the army. Dr. S. E. Jelliffe has been appointed librarian.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 9, 1894:

DISEASES.	Week ending Jan. 2. Week ending Jan. 9.			
	(8464	Deaths.	Сакев.	Deaths.
Typhus	0	0	()	()
Typhoid fever	4	::	10	5
Searlet fever.	125	- 6	96	11
Cerebro-spinal meningitis	0	1	1	2
Measles	293	. 7	491	29
Diphtheria	213	37	559	55
Small-pox		2	12	2

The Johns Hopkins University.—The medical class numbers seventeen, and forty-six medical graduates are attending the post-graduate lectures.

The New York Post-graduate Clinical Society.—The special order for the meeting of the 6th inst. was a paper on Severe Hæmorrhages from the Nose, by Dr. Wolff Freudenthal.

The Home for Consumptives is remembered in the will of the late Stephen Wilcox by a bequest amounting to \$10,000.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 24, 1893, to January 6, 1894:

HALL, John D., Major and Surgeon, by direction of the Secretary of War, is granted leave of absence for two months, to take effect on or about January 15, 1894, with permission to apply for an extension of one month.

MUNSON, EDWARD L., First Lieutenant and Assistant Surgeon, is relieved from duty at Jefferson Barracks, Missouri, and will report in person to the commanding officer, Fort Assinniboine, Montana, for duty at that post.

Naval Intelligence,—Official List of Changes in the Medical Corps of the United States Navy for the week ending January 6, 1894.

COOK, FRANK C., Washington, D. C., commissioned an assistant surgeon in the navy January 4, 1894.

### Society Meetings for the Coming Week:

MONDAY, January 15th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesday, January 16th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Medical Societies of the Counties of Franklin (annual), Kings (annual), Otsego (semi-annual-Cooperstown), and Westchester, N. Y.; Ogdensburgh, N. Y., Medical Association; Connecticut River Valley Medical Association (Bellows Falls), Vt.; Baltimore Academy of Medicine.

Wednesday, January 17th: New York Academy of Medicine (Section in Public Health and Hygiene); Harlem Medical Association of the City of New York; Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, January 18th: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, January 19th: New York Academy of Medicine (Section in Orthopædic Surgery); Baltimore Clinical Society; Chicago Gynæcological Society.

Saturday, January 20th: Clinical Society of the New York Post-graduate Medical School and Hospital.

## Answers to Correspondents:

No.420.—Several years ago an attempt was made to secure the enactment of such a law, but we are quite sure that it failed.

# Wetters to the Editor.

#### TRIONAL.

Brooklyn, January 1, 1894.

To the Editor of the New York Medical Journal:

Six: Trional is the best hypnotic, in my opinion. One year ago my experience with it began, and since then I have given it hundreds of times, with a result so satisfactory that I am impelled to pronounce it, as a soporific pure and simple, without a peer. This opinion is of more than common worth, for it is the outcome of its use under conditions pre-eminently adapted to test the value of any hypnotic—as the agrypnia attending the early abstinence time of narcotic inchriety is only equaled by the insomnia of the insane. It, then, may be deemed certain that its claim to merit is well founded if it serves this purpose in each of these special conditions; and there is a large and enlarging consensus of opinion among alienistic experts that, of all sedstive soporifies, trional leads the list.

The most extensive paper in English, and one of the earliest on trional, was read by myself before the Brooklyn Neurological Society on April 12, 1893, in which reference was made to its use a hundred times, with success in ninety instances. This result tallied closely with reports made by foreign physicians, and my success since then has been so satisfactory that I now employ trional to the exclusion of all other soporifies during the time when the need for a powerful hypnotic is most pronounced.

In my paper certain details were noted which need not now be cited, inasmuch as a reprint is at the command of any one having enough interest in the subject to request it.

During the last six months several papers on trional by foreign observers—Beyer, Cainer, Collaz, Garnier, Hammerschlag, Koppers, Randa, and Pelander—have been presented, all adding to the good opinion of earlier observers.

Let it be distinctly understood that trional is not an anodyne. A full appreciation of this fact is of prime importance. It has no analgesic power; if pain is present, sleep will not come. This, I fancy—or often an underdose—is the main reason why non-success has been noted by some.

When painful conditions obtain, to combine it with codeine -codeine, not morphine—will secure a happy result; or, if the opiate is not needed, phenacetin makes an admirable adjunct

As compared with sulphonal—its nearest rival—the effect of trional is prompter, more pronounced, more prolonged. It is, too, more certain. My experience with sulphonal has made me think it an erratic sort of drug.

Compared with chloral, trional is safer. Chloral has killed, and not infrequently in doses usually deemed safe. I am not aware of any such charge against trional. No auxiety attends my giving it, whereas with chloral, though I have not noted a lethal result, I have never been free from a certain solicitude regarding the outcome of its taking.

Compared with paraldehyde, its effect is more decided and more lasting, and its freedom from the latter's villainous

smell and taste is no small advantage. Chloralamide and somnal—in each of which the main factor is chloral—are less potent than trional.

In closing, one point touching this topic is worth noting. Most of those who honor me with their care are medical men. The aggregate experience of these gentlemen regarding the effect of various hypnotics upon themselves is not small, and without exception, save one—a case cited in my paper, in which failure was due less to the drug than to the doctor—they have pronounced trional the most satisfactory soporific they ever used.

J. B. Mattison, M. D.

# Proceedings of Societies.

## NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYN. ECOLOGY.

Meeting of December 28, 1893.

Dr. H. J. BOLDT in the Chair.

Absence of Menstruation, -Dr. Hubbard W. Mitchell reported the history of a case which presented the following features: The patient, a young woman, twenty-four years of age, came under the speaker's notice first in February, 1892, complaining of approaching insanity, which she was sure would come on, from the fact that she had never menstruated. A thorough physical examination was made, and, with the exception of infantile development of the uterus, the patient was found in every respect in perfect health. Her fears as to her mental condition were allayed, and she had up to the present time continued to act in the capacity of a governess. In October, 1893, she had a molar extracted, and the operation was followed by considerable hæmorrhage from the cavity for some time afterward. At one time the hemorrhage was so great as to cause unconsciousness and almost exsanguinate the patient. It was almost a month before she had regained her usual health. The condition, the speaker thought, might be one of hæmophilia. Up to the time of the tooth extraction there had been no vicarious menstruation or natural flow, and the patient had enjoyed perfect health. At the present writing she was in good condition and following her usual vocation.

Specimens of Calculi.—Dr. Locke presented some specimens of calculi which had been passed by a patient upon whom an operation for suppurating ovarian tumor had been performed a year previously. The patient had improved in health until December, 1893, when she was seized with a severe attack of tenesmus, and finally passed the calculi. The speaker believed them to have formed on silk ligatures acting as nuclei.

Accouchement Forcé.—Dr. S. Marx read a paper on this subject. After reviewing the bistory of other methods of hastening delivery he described the steps in the operation of accouchement forcé as practiced by Dr. Grandin and himself. The operation was divided into two stages, the preparatory and the operative. The first stage might in some cases be omitted, as where the cervix was dilatable or where the os was soft, non-resisting, and boggy, as occurred in placenta prævia. It was especially in this complication that the operation was indicated and was most easily done. The operation having been decided upon, the patient was placed on the back, no anæsthetic being necessary. After thorough asepticism of the vagina, cervical canal, and external genitals, a Sims's speculum was introduced and the anterior or posterior lip was seized with a bullet forceps, and iodoform gauze cut in strips of the width of two

fingers was carried in the grasp of a Garrigues's intra uterine tampon forceps into the cervical canal. The next step was to slowly and gently insinuate the instrument until the gauze was well in the canal or until it met with resistance from the presenting foetal part, most frequently the head. The canal was then tamponed as completely as possible. The vaginal vault and vagina were tamponed in the usual way and the patient was put to bed. This method of tamponing the cervix was very important, and upon it the success or failure of the operation depended. It had for its objects, first, to separate the membranes mechanically without endangering their integrity; secondly, to materially soften the cervix and cause a marked disappearance of the vaginal portion; thirdly, to provoke uterine pains, and it sometimes gave rise to sufficient uterine action to effect spontaneous delivery. The patients usually complained of intermittent, crampy pain, which indicated uterine action. In from ten to fifteen bours the tampon was to be removed, the patient thoroughly douched, and an anæsthetic given. The os would now be found very soft and dilatable, so as to admit one or two fingers readily, and the hand was to be introduced into the vagina, one finger after the other being gently inserted, until the open hand could be brought up to the cervix. The hand was then to be closed and gently withdrawn. If it was withdrawn rapidly, it was easy to imagine, the uterus might readily be ruptured. The closed hand acted like Tarnier's dilating bags, which were introduced empty into the uterus and slowly withdrawn. After withdrawing the closed fist several times, until no resistance on the part of the cervix was encountered, it would be found that it was sufficiently dilated for the passage of an ordinary child. The membranes having been preserved, version, if indicated, was easily done and the labor terminated. The uterine tampon, in the absence of hæmorrhage or sepsis, was entirely optional with the operator. A number of cases were reported by the speaker in which the advantage of the operation was shown. The cases had not been selected, and the method had been tried faithfully upon women as the indications had happened to present themselves, The rate of mortality had been practically nil,

Dr. E. H. Grandin thought that the reader of the paper bad formulated very clearly the reasons for such an operation as accouchement forcé. As it was eminently a safe procedure, both to the mother and to the child, it surely ought to be given a fair trial until something better was presented. The only objection that could be made to the operation was the danger of rupture, but as that was not confined to accouchement force, but was present in versions and forceps deliveries, it ought not to stand in the way of the employment of the procedure. Out of a series of sixteen cases treated by this method, there had been no deaths of mothers and a loss of only two of the infants. The name indicated force, but, as a matter of fact, no force was used; it was simply a yielding of the muscle to continued pressure. If rupture did occur to the cervix, that could be repaired at once by placing the patient on the back and drawing the cervix down into view, so that the extent of the injury could be accurately appreciated. The cases in which the operation was called for were those of placenta prævia and impending uræmia, and in these grave conditions the speaker's mortality rate had been nil. If the cases were treated in a scientific manner, no woman ought to be allowed to die from sepsis. The speaker thought that the treatment of eclampsia with morphine and other drugs was generally bad practice; what was wanted was to empty the uterus as soon as possible and eliminate the poison.

Dr. Malcolm McLean said that he did not understand the term acconchement force as applied to the operation described by Dr. Marx. He could see nothing in it but induced labor;

slow dilatation surely could not be accouchement forcé. As for the use of iodoform gauze for packing, he did not see that it had any advantage over the hydrostatic dilators. He thought that in primiparae it would be found that usually the canal was too small to admit of the introduction of the hand without danger of tearing the cervix, and in these cases he was in favor of using the dilators. It certainly required good judgment on the part of the attending physician as to whether cases were suitable for the operation or not, and, further, no man who was capable of undertaking accouchement forcé should have rupture result from his manipulations.

Dr. J. CLIFTON EDGAR said that his experience with the eperation had led him to the conclusion that it was a much more serious procedure than was generally supposed, and he would resort to it only where there was imminent danger to mother or child.

Dr. Robert A. Mueray did not believe in the feasibility of dilating with the fingers; they were apt to become cramped with the strained position, and, if they were withdrawn to allow of rest, the parts would retract. It might be carried out where one had trained assistants to relieve him, but for his part he preferred to use the dilators, as they had always given satisfaction. Much harm might be done by emptying the uterus too rapidly, as it was often followed by fatal shock.

The Radical Cure of Umbilical Hernia.—Dr. George M. EDEBOHLS demonstrated his method of performing this operation. In true umbilical hernia the opening was round and usually large, from an inch to four inches in diameter, and the sur rounding tissue was fibrous. It was for this reason that the operation so frequently failed. The size of the opening, the fibrous structure to deal with, and the enormous tension that must necessarily be brought to bear on the parts to keep them together, had often led to the question, Could there be a radical cure of umbilical hernia? The speaker believed that his method offered the best solution of the difficulty. It would not cure in every case, but the number of cures had been sufficiently large to justify him in the operation. When one considered the liability of these herniæ to injury and inflammation and consequent adhesions, and the danger of their becoming irreducible, he thought that the woman ought to have a chance for her life, and it was certainly offered in his operation. The operation consisted in splitting back a flap on each side of the opening and bringing the surfaces together by means of silkworm-gut suture in such a manner that the surfaces were apposed without puckering them together, as had previously been done. The suture was buried in the part and allowed to remain for an indefinite period. It was to the permanent buried suture, supporting the parts, that the speaker believed the success in his cases had been due. He described four cases of true umbilical hernia. In three of them the operation had been successful; in the fourth recurrence had taken place in twelve months.

Hysterical Manifestations due to Alcohol.—Dr. Henry C. Cor read a paper with this title. Every practitioner, he said, occasionally encountered cases of hysteria of obscure origin, occurring, it might be, in patients who were not previously suspected of being particularly neurotic. Usually a careful review of the history or the discovery of some unusual cause of excitement explained the phenomena satisfactorily, but sometimes the outbreak was so violent as to suggest a different influence. In a certain class of women one was prepared to come in contact with frequent cases of inebriety with unmistakable symptoms, but we were seldom on the lookout for them among highly respectable women. That tippling was a common practice among fashionable women was well known. They resorted to stimulants in order to support the strain incident to their exciting and irregular mode of life. It was seldom that

the effect was visible except in an unnatural vivacity, the source of which was suspected only by a practiced eye. It would only be after unwonted indulgence that the old hands would lose control of themselves and display such actions as might readily be mistaken for those of pure hysteria. For, it should be remembered, the stage of exhilaration manifested in men by hilarity, loud talking, confusion of ideas, etc., often found its expression in women in complex phenomena which were included under the head of hysteria. The subjects were usually of a distinctly nervous type. The speaker had found that the cases could be classified under two heads: First, those in which young women, naturally well balanced, unaccustomed to the use of alcohol, took an amount which, for them at least, was excessive. Second, older women of a neurotic type who were accustomed to use spirits more or less freely. Several cases were given in detail to show the peculiar manifestations of an attack of hysteria due to alcohol. The speaker wanted to emphasize the following points: In every case of supposed hysteria to which one was summoned for the first time it was wise to ask if the manifestations might not be directly due to the use of stimulants, either with or without the knowledge of the patient's family. Considerable tact was often necessary in order not to arouse the suspicions of the family, who might be entirely ignorant of her failing. A frank conversation with the patient when she was in her normal condition was more likely to be attended with good result than a hasty and injudicious reprimand at the time. It was important to remember that a small amount of alcohol might be sufficient to upset a woman who was not an habitual tippler. The diagnosis might present great difficulties, especially in the case of a strange patient, or one who gave a previous history of hysteria, particularly at the time of the menstrual period, when so many women used spirits for the relief of dysmenorrhea. Certain phenomena of true hysteria were usually absent in those who were under the effects of alcohol, such as visceral manifestations, areas of anæsthesia, paralyses, contractures, etc. The patients were not in a condition to practice successfully the various deceptions with which the physician was so familiar. Exaltation was more marked than depression. In regard to the prognosis, the alarmed family could be assured that nothing serious was the matter, but that the patient was suffering from an ordinary nervous attack from which she would speedily recover. The question of her future was a more serious one, to be determined by the frequency of the attacks and her power to control the craving for stimulants and to resist temptation to resort to chloral, morphine, and other drugs. The ordinary treatment of an hysterical attack was useless in the alcoholic cases. The stomach was only upset without relief being produced. If the patient could sleep soundly, she would soon regain her equilibrium, and for this purpose the speaker had found nothing better than the old-fashioned Dover's powder. Morphine hypodermically usually excited the patients much more and made the condition worse. The question of subsequent treatment of such cases was an important one. A sensible woman who had unwittingly overstimulated herself would be so mortified that she would carefully guard against any repetition. The family physician was in a position to exert a strong influence in the right direction. He should not only warn his patients against the pernicious effects of tippling, but discourage the common practice of administering spirits freely to young girls at the menstrual period. Cases of inebriety were clearly traceable to such a practice. It was hardly necessary to add that the physician who prescribed a drink of whisky or brandy for every slight ailment assumed a responsibility only a little less than that taken by the one who gave an injection of morphine under similar circumstances.

# Book Antices.

Clinical Gynæcology: being a Handbook of Diseases Peculiar to Women. By Thomas More Madden, M. D., F. R. C. S. Ed., Obstetric Physician and Gynæcologist. Mater Misericordiæ Hospital, Dublin, etc. With Two Hundred and Fiftynine Illustrations. Philadelphia: J. B. Lippincott Company, 1898. Pp. xvi-11 to 562. [Price, \$4.]

In the pages of this volume the author has embodied the results of his experience, that extends over a quarter of a century, in diseases peculiar to women. The work, therefore, is an account of what he has personally observed at the bedside, or carried into effect in the treatment of gynæcological cases, and he presents it to the reader in the colloquial form of lectures.

In his opening lecture he says that he will not refer as incessantly as some teachers do to those German and French gynæcologists whose authority is so much relied on in some places; but, if further light is needed as a guide in the often dark and difficult paths of gynæcology, to America he can best turn for guidance, because modern gynæcology unquestionably owes its present development chiefly to the influence and teaching of the American and British schools of medicine.

After describing the instruments and technique necessary for examining patients, the author proceeds to a consideration of the injuries of the perinæum. In his experience, perineal lacerations are less frequent than heretofore, a result that is largely due to abstention from unnecessary interference with the perinæum during the second stage of labor. He prefers Duke's method of perinæorrhaphy, in which a double-edged bistoury is made to penetrate the tissues in front of the anus at right angles to the vulva for two inches and a half upward, and as the knife is withdrawn the incision is enlarged laterally to two inches. The patient is changed from the lithotomy posture to a lateral decubitus, and, the points of the incision being pressed together, a lozenge-shaped opening is seen, and the cut surfaces are coaptated and sutured. There is no loss of tissue, no danger of hæmorrhage, and no communication with the vagina or rectum, and we believe that in certain cases this operation will be found as satisfactory as it is ingenious.

The author agrees with Dr. Andrew F. Currier that malignant disease of the vulva offers peculiarly good opportunities for radical treatment, and that it should be oftener resorted to.

He states that his title to priority in the treatment of cystitis by rapid dilatation of the urethra is based on the employment of that procedure as early as 1875, and says he was unaware that it had been suggested by Goodell or any one else. The operation is not uniformly successful, but he has found it of vast benefit in the treatment of a large number of cases of that disease.

Dr. Madden considers that the removal of the uterine appendages for fibromyomata is rarely necessary. Electricity has failed to remove the tumor in any case in which he has employed it. He advocates the usual palliative measures.

He does not regard the abdominal or vaginal extirpation of the cancerous uterus as expedient or justifiable as a general rule of practice; the enormous mortality of the operations suggests the desirability of employing palliative measures for the remainder of the patient's life. She should be allowed to die naturally, not surgically.

In discussing the question of the removal of the appendages he says: "The question of election or necessity I regard as the cardinal point to be decided in considering the expediency of removing the uterine annexa in the treatment of Falloppiantube disease. In many instances, unquestionably, that course

becomes a necessity. It should never be forgotten, however, that in probably a no less large number of cases tubal diseases may also be successfully treated by some of the remedially effectual conservative measures to which reference has been made."

Throughout the text the author shows that he is free from the furor secandi, and the broad spirit in which the various topics in gynacology are discussed, the judicious counsel that is given regarding a choice of procedures, and the sensible conservatism that is so noticeable a feature of the work commend it to the attention of the practitioner as well as the student.

## BOOKS, ETC., RECEIVED.

A Treatise on the Medical Jurisprudence of Insanity. By Edward C. Mann, M. D., Author of A Manual of Psychological Medicine. Albany, N. Y.: Matthew Bender, 1893. Pp. xxv-420.

Essentials of Practice of Medicine. Arranged in the Form of Questions and Answers. Prepared especially for Students of Medicine. By Henry Morris, M. D., Late Demonstrator, Jefferson Medical College, Philadelphia, etc. With a very complete Appendix on the Examination of Urine, by Lawrence Wolff, M. D., Demonstrator of Chemistry, Jefferson Medical College. Colored (Vogel) Urine Scale and Numerous Illustrations. Third Edition, revised and enlarged by some Three Hundred Essential Formulæ, selected from the Writings of the most eminent Authorities of the Medical Profession. Collected and arranged by William M. Powell, M. D., Attending Physician to the Mercer House for Invalid Women at Atlantic City, N. J. Philadelphia: W. B. Saunders, 1894. Pp. xv-17 to 374. [Price, §2.] [Saunders's Question Compends.]

The Physiology of Death from Traumatic Fever. A Study in Abdominal Surgery. By John D. Malcolm, M. B., C. M., Fellow of the Royal College of Surgeons of Edinburgh, etc. London: J. & A. Churchill, 1893. Pp. iv-129. [Price, 3s. 6d.]

Syllabus of Lectures on the Practice of Surgery. Arranged in Conformity with the American Text-book of Surgery. By N. Senn, M. D., Ph. D., LL. D. (Chicago), Professor of the Practice of Surgery and Clinical Surgery in Rush Medical College, etc. Philadelphia: W. B. Saunders, 1894. Pp. 6-17 to 221. [Price, \$2.]

Manual of Physical Diagnosis. For the Use of Students and Physicians. By James Tyson, M. D., Professor of Clinical Medicine in the University of Pennsylvania, etc. Second Edition, revised and enlarged. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xi-9 to 241. [Price, \$1.50.]

Myxœdema: and the Effects of Climate on the Disease. By A. Marius Wilson, M. D., B. S. Durb., L. R. C. P. Lond., M. R. C. S. Eng. London: The Scientific Press, Limited, 1894. Pp. 9 to 36. [Price, 2 shillings.]

The Art of Living in Australia (together with Three Hundred Australian Cookery Recipes and Accessory Kitchen Information by Mrs. H. Wicken, Lecturer on Cookery to the Technical College, Sydney). By Philip E. Muskett, Late Surgeon to the Sydney Hospital, etc. London, Edinburgh, Glasgow, Melbourne, Sydney, and New York: Eyre and Spottiswoode, 1893. Pp. xxix-3 to 431.

Die Schwankungen der Reizzustands-Grösse, d. i. der Intensität, bezw. des Umfangs des Lebens im menschlichen Körper. Experimental-Untersuchungen von Dr. K. Francke, Specialarzt für innere Leiden. Mit 98 Abbildungen. Leipsic: Georg Thieme, 1893. Pp. 7-9 to 32. [Preis, M. 15.]

Mechanical Aids in the Treatment of Chronic Forms of Disease. By George H. Taylor, M. D., etc. New York: George W. Rodgers, 1893. Pp. 109. Microscopical Studies in Pelvic Peritonitis. By Mary A. Dixon Jones, M. D., Brooklyn, N. Y. [Reprinted from the Medical Record.]

Carcinoma of the Floor of the Pelvis. By Mary A. Dixon Jones, M. D., Brooklyn, N. Y. [Reprinted from the *Medical Record.*]

Sterility in Woman. Causes, Treatment, and Illustrative Cases. By Mary A. Dixon Jones, M. D. [Reprinted from the Medical Record.]

Colpo-hysterectomy for Malignant Disease. Some Considerations in regard to the Operation, Technique, etc. With a Report of my First Five Cases. By Mary A. Dixon Jones, M.D., Brooklyn, N.Y. [Reprinted from the American Journal of Obstetrics and Diseases of Women and Children.]

Diagnosis and Some of the Clinical Aspects of Gyroma and Endothelioma of the Ovary. By Mary A. Dixon Jones, M. D., Brooklyn, N. Y. [Reprinted from the Buffalo Medical and Surgical Journal.]

Movements of the Upper Eyelid associated with Lateral Movements of the Eyeball. By Dr. Harry Friedenwald, Baltimore, Md. [Reprinted from the Archives of Ophthalmology.]

A Few Points of Interest to the Family Physician. By Joseph Eastman, M. D., LL. D., Indianapolis, Ind. Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association. [Reprinted from the Journal of the American Medical Association.]

Abdominal Surgery and its Evolution and Involution. By Joseph Eastman, M.D., Indianapolis, Ind. [Reprinted from the Journal of the American Association.]

Vaginal Extirpation of the Uterus. Forty Consecutive Cases. By Joseph Eastman, M.D., Indianapolis, Ind. [Reprinted from the *Medical Record*.]

Studies and Methods in Suprapubic Hysterectomy. By Joseph Eastman, M. D., Indianapolis, Ind. [Reprinted from the North American Practitioner.]

Artificial Opening of Pulmonary Cavities, Insertion of Rubber Tube, and Injection of Chlorine Gas. By E. L. Shurly, M. D., Detroit, Mich. [Reprinted from the Journal of the American Medical Association.

Medicine as a Career for Educated Men. The Commencement Address at Lafayette College, June 13, 1893. By William W. Keen, M. D., Philadelphia.

Habits of Posture a Cause of Deformity and Displacement of the Uterus. By Eliza M. Mosher, M.D., Brooklyn, N. Y. [Reprinted from the New York Journal of Gynæcology and Obstetrics.]

Appendicitis: A Personal Experience. By Howard Crutcher, M. D., Ohicago. [Reprinted from the *Journal of Orificial Surgery*.]

Glycosuria as an Additional Symptom indicating the Neurotic Origin of Dermatitis Herpetiformis (Dubring). By James McF. Winfield, M. D. [Reprinted from the Journal of Cutaneous and Genito-varinary Diseases.]

On the Microbic Origin of Chorea. Report of a Case, with Autopsy. By Charles L. Dana, A.M., M. D. [Reprinted from the American Journal of the Medical Sciences.]

Mensuration in the Physical Diagnosis of Pulmonary Phthisis. By George A. Evans, M. D. [Reprinted from the Brooklyn Medical Journal.]

Supravaginal Hysterectomy without Ligature of the Cervix, in Operation for Uterine Fibroids. A New Method. Cases of Chronic Ovarian Abscess, illustrating the Danger of Delay in their Proper Management. Drainage in Abdominal Surgery; its Unnecessary and Excessive Use. By B. F. Baer, M. D., Phila-

delphia. [Reprinted from the Transactions of the American Gynæcological Society and the Philadelphia Polyclinic.]

A Supplementary Paper upon Supravaginal Hysterectomy by the New Method, with Report of Additional Cases. By F. Baer, M. D., Philadelphia. [Reprinted from the Transactions of the American Gynacological Society.]

What are the Indications for Abdominal Section in Intrapelvic Hamorrhage? By Marcus Rosenwasser, M. D., Cleveland, Ohio. [Reprinted from the Transactions of the American Association of Obstetricians and Gynacologists.]

On Arsenical Paralysis. By S. E. Henschen. With One Plate. (Presented to the Royal Society of Sciences of Upsala, September 30, 1893.)

Apparatus for Recording the Curve of Rotation in Scoliosis. By L. A. Weigel, M. D. [Reprinted from the American Medicosurgical Bulletin.]

Horsehair in Minor Surgery. By C. O. Thompson, M. D., Boston. [Reprinted from the Boston Medical and Surgical Journal.]

A New Pathology and Treatment of Nervous Catarrh. By Seth Scott Bishop, M. D., Chicago. [Reprinted from the Journal of the American Medical Association.]

Two Cases of Laryngeal Neoplasms. By Robert Levy, M.D. [Reprinted from the Journal of the American Medical Association.]

Fifth Annual Report of the Health Department of Mansfield, Ohio, 1892 to 1893.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Ninety-fifth Annual Session, held at Baltimore, Md., April, 1893. Also Semi-annual Session, held at Easton, Md., November, 1892.

A Manual of Practical Hygiene, designed for Sanitary and Health Officers, Practitioners, and Students of Medicine. By W. M. L. Coplin, M. D., Adjunct Professor of Hygiene, Demonstrator of Pathology, and Curator of the Museum, Jefferson Medical College, etc., and D. Bevan, M. D., Instructor in Hygiene and Clinical Microscopy, Jefferson Medical College, etc. With an Introduction by H. A. Hare, M. D., Professor of Therapeutics, Materia Medica, and Hygiene in Jefferson Medical College, Philadelphia. With One Hundred and Forty Illustrations, many of which are printed in Colors. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xvi-25 to 456. [Price, &4.]

An American Text-book of Gynæcology, Medical and Surgical, for Practitioners and Students. By Henry T. Byford, M. D., J. M. Baldy, M. D., Edwin B. Cragin, M. D., J. H. Etheridge, M. D., William Goodell, M. D., Howard A. Kelty, M. D., Florian Krug, M. D., E. E. Montgomery, M. D., William R. Pryor, M. D., George M. Tuttle, M. D. Edited by J. M. Baldy, M. D. With Three Hundred and Sixty Illustrations in Text, and Thirty-seven Colored and Half-tone Plates. Philadelpbia: W. B. Saunders, 1894. Pp. xxiv-17 to 713. [Price, \$6.00.]

The Healing of Rodent Cancer by Electricity. By J. Inglis-Parsons, M. D., M. R. C. S., M. R. C. P. (Lond.), etc. London: John Bale & Sons, 1893. Pp. vii-82. [Price, 5 shillings.]

Twelfth Annual Report of the State Board of Health of New York, Transmitted to the Legislature, February, 1892.

Thirteenth Annual Report of the State Board of Health of New York. Transmitted to the Legislature, March 9, 1893.

Pharyngites hémorrhagiques. Par le Dr. Marcel Natier, Chef du service du nez, des oreilles et du larynx de la Policlinique de Paris. [Extrait de la Revue internationale de rhinologie, otologie et laryngologie.]

# Miscellany.

The Treatment of Whooping-cough,-Dr. H. Méry contributes to the Gazette médicale de Paris for December 9th an article of which the following is the substance: There is no specific treatment for whooping-cough; the multiplicity of plans of treatment recommended testifies to the restricted extent of their value. Without professing to recount them all, we may divide them into several great groups, each, as a rule, founded upon the pathogeny of the disease. Accordingly, the abundance of antispasmodic plans of treatment springs from the nervous theory of whooping-cough, which was for a long time the only one entertained; with the theory of infection came attempts at general and local antiseptic treatment; with the theory that designates a reflex starting from the mucous membrane as the cause of whooping-cough came nasal insufflations of powders, recently in vogue. At the outset the plans of treatment may be divided into the general (internal medication) and the local (by sprays, paintings of the throat, and nasal insufflations). As regards internal medication, there are two great groups of medicaments. The first consists of the antispasmodies, including belladonna and its derivatives, so vaunted by Trousseau, antipyrine, potassium bromide, opium, codeine, chloral, and syrup of ether. The second consists of antiseptic drugs, such as quinine sulphate, carbolic acid, and bromoform. Some of these, such as carbolic acid, act in addition as calmatives. Certain other drugs that it is not easy to class in either of these two groups have been employed in whooping-cough. Among these are tincture of drosera, oxymel of squill, and terpene, which are specially intended to subdue the catarrhal elements of the third stage. In the local treatment calmatives and antiseptics have been used to about the same extent. Chief among them are spraying with salicylate of sodium, with carbolic acid, or with resorcin, inhalations of chloroform or ether, applications of cocaine to the pharynx, applications of resorcin within the larynx, and, finally, insufflations of powders into the nasal fossæ. The author then alludes to the occasional success of vaccination in arresting the course of whooping-cough.

In the presence of a case of confirmed whooping-cough, he says, the following advice may be given: As regards internal medication, the preference should be accorded to antipyrine. Most authors advise the administration daily of about a grain and a half for each year of the patient's age, but the author is of the opinion, with Sevestre, that this amount is too small; antipyrine should be used in whooping-cough in daily amounts of

fifteen, thirty, or forty-five grains, as in chorea. In children over two years old doses of eight grains may be given, repeated three, four, or five times or more, according to circumstances; in those under two years old the doses should be only three grains, repeated two or three times a day; in children under a year old the daily quantity need not exceed eight grains. If the maximum doses mentioned are given, the child must be watched closely. As a consequence of the administration of antipyrine a decided amelioration of the number and violence of the paroxysms will generally be seen to occur; at the end of a few days, when this amelioration has taken place, the use of antipyrine must be suspended, and it may be resumed after several days of rest. If the use of antipyrine is continued uninterruptedly, it ceases to have any effect at the end of a certain length of time. By suspending it, however, one has the advantage throughout the whole duration of the disease of a trustworthy remedy. While antipyrine is accorded the first place as a remedy, we must have at our disposal other drugs capable of supplementing it, especially at the times when we are obliged to suspend its use. Among these is belladonna, especially neutral atropine sulphate in a solution of 1 to 1,000. This solution should be used in small doses at first, beginning with one or two drops, and the daily amounts are to be increased very carefully up to six drops for children over a year old. This treatment gives rise to a few accidents, so it is necessary to keep watch of the pupils and discontinue the use of the remedy and diminish the doses if there is contraction of the pupils. Tincture of drosera, in daily amounts of from twelve to thirty drops, sometimes gives good results, and it also may take the place of antipyrine. In a disease of such long duration and one against which there is no specific we must have a number of drugs with which we can ring the changes when one or another of them shows itself inactive. We can hardly abbreviate the duration of an attack of whoopingcough, so our only function is that of mitigating its intensity. Bromoform at present has a great reputation in Germany, and has been employed successfully in France by M. Huchard. Unfortunately, this drug has several times given rise to accidents and even to death, so that the author hesitates to recommend it. It is used in doses of from two to four drops three times a day, according to the patient's age.

In regard to local treatment, the author considers that in general it is not to be resorted to unless the internal treatment proves inadequate; if the paroxysms are exceedingly violent, one may resort to penciling/the pharynx twice a day with a solution of one part of cocaine hydrochloride in twenty parts of water. It is best to abstain from irritating the throat with other local applications, and, moreover, up to the present time they have not yielded results superior to those of other methods of treatment. Spraying with various solutions—such as those of carbolic acid, sodium salicylate, and resorcin—may be employed too, but only as accessory measures.

The treatment at the time of a paroxysm requires that the child should be made to sit down with its head held in the hand. Sometimes, especially in very young children, it is necessary to provoke artificially the expulsion of mucus that accumulates in the lower part of the throat. If the paroxysms are very prolonged and if there is a tendency to convulsions, inhalations of chloroform or ether should be employed at the onset of each paroxysm. Very violent paroxysms may threaten suffocation or fainting; in either case artificial respiration should be resorted to.

The question of whether or not children affected with whooping-cough should be allowed to go outdoors has been much discussed. M. Sevestre thinks that it should be answered in the negative as regards cases of the disease that are at all

serious; but in cases of a light attack, especially in summer, one need not be so severe. The slightest bronchial inflammation, however, should cause us to forbid the patient's going out, no matter what the weather may be. It is too often the case that the frequency of the paroxysms increases after going out. The diet of whooping-cough patients demands a good deal of attention. If the paroxysms cause the food to be vomited, we should try to arrest them by giving eight grains of potassium bromide half an hour before the meal and from one to three grains of menthol at the conclusion of the meal, in alcoholic solution. Moreover, the food should be solid and of a nature to be assimilated rapidly. It should be given immediately after a paroxysm. Thus the child will be able to take a number of little meals in the course of the day. When, by reason of the measures mentioned, the whooping-cough is plainly on the decline, change of air may lead to its rapid and sudden cessation. But the important thing is not to advise this measure too early. The catarrhal element which accompanies whooping-cough, especially toward the end, has its special indications. Ipecac may be used when there is an excessive accumulation of secretions in the bronchial tubes, also oxymel of squill. The dilatation of the bronchi and the chronic catarrh which follow grave cases of whooping-cough are to be treated with terpene, eucalyptus, etc. At this stage also good results are obtained by the use of baths of compressed air. Finally, some prophylactic treatment should be followed as in the other infectious diseases, especially if there are other young children in the family. The prevention of whooping cough is another object to be gained by not allowing patients to go out; the public gardens of Paris, where numerous children meet, are indeed the most frequent scenes of the propagation of this disease.

The Great Medical Error of the Day.—In an article with this title, published in the January number of the University Medical Magazine, Dr. William Goodell, of Philadelphia, says:

"In the treatment of the diseases of women at the present time there seems to me to be a tendency to lay too much stress upon lesions of the reproductive organs. Too little heed is therefore given to the nerve element of woman's diseases, and as a natural sequence the surgical feelers and antenne of the medical profession, always too keenly sensitive, vibrate vehemently at the approach of an ailing woman. This trend of the profession, to appeal to the knife as the great panaeca for woman's diseases, is seen everywhere. It prevails alike in city, town, village, and hamlet. It asserts itself in every medical discussion, and stands out in bold relief upon the pages of every medical journal. It has caused many needless sexual mutilations and unnecessary operations, and it is, in my opinion, the great medical error of the day.

"It comes, not so much from the glamour surrounding surgery, nor from the greed of gold, but from errors of judgment and from mistaken diagnosis. These arise from the fact that woman, through her sensitive and emotional organization, is a bandle of contradictions. More pitiful than man, and more long-suffering, her anger is more cruel, and her jealousy more relentless. Feebler than man, an appeal to her affection will make her surpass him in sheer muscular endurance. Who can nurse her kin so untiringly and with so little rest as even a frail woman can? What father can equal a mother in fondling and soothing a sick and fretful child through the weary night watches? What man can undergo the sheer fatigue, the strain and stress that a woman will for those she loves? Even in her pleasures, her physical amusements, she will, through keen enjoyment, often outtire the strongest man. In one word, she is a creature of impulse and of emotion. But all nerve strains, whether arising from the emotions, from the affections, or from the passions,

have their reactions, and very strange and very misleading reflexes come from the loss of brain control over insubordinate lower nerve centers. For what is hysteria but nerve misrule and the panic of the brain at incompetent control? The secret and sanctity of woman's inner life lies in her affections, and what disturbs them disturbs the nerves, and through them their environment of flesh and blood. These unruly nerve lights flashing and fading at their own will, and without control in the different organs of the body, the most careless observer may sometimes plainly see, for the clew is then as secure as the steps of a geometrical problem. But then again the symptoms are more frequently obscure. Often they are as misleading as the lapwing's flight. To construe such symptoms, to unfold their sense, and to paraphrase them, so as to gain a true conception of their character, often demands a deep acquaintance with human life and a keen insight into the most secret springs of its action. . . .

"Nerve strain, or nerve exhaustion, comes largely from the frets, the griefs, the jealousies, the worries, the bustles, the carks and cares of life. Yet, strangely enough, the most common symptoms of this form of nerve disorder in women are the very ones which lay tradition and dogmatic empiricism attribute to ailments of the womb. They are, in the usual order of their frequency, great weariness, and more or less of nervousness, and of wakefulness; inability to walk any distance and a bearingdown feeling; then headache, napeache, and backache. Next comes scant, or painful, or delayed, or suppressed menstruation; cold feet and an irritable bladder; general spinal and pelvic soreness and pain in one ovary, usually the left, or in both ovaries. The sense of exhaustion is a remarkable one; the woman is always tired; she spends the day tired, she goes to bed tired, and she wakes up tired; often, indeed, more tired than when she fell asleep. She sighs a great deal, she has low spirits, and she often fancies that she will lose her mind. Her arms and legs become numb so frequently that she fears palsy or paralysis. Nor does the skin escape the general sympathy. It becomes dry, harsh, and scurfy, and pigmentary deposits appear under the eyes, around the nipples, and on the chin and forehead. Blondes are likely to get a mottled complexion, and brunettes to be disfigured by brown patches or by general bronzing. Sometimes the whole complexion changes to a darker hue, and an abnormal and a disfiguring growth of hair appears on the face. There are many other symptoms of nerve strain, but since they are not so distinctly uterine in expression, and therefore not so misleading, I shall not enumerate them.

"Now, let a nervous woman, with some of the foregoing symptoms, recount them to a female friend, and she will be told she has 'womb disease.' Let her consult a physician, and he, especially if she has backache, bearing down feelings, an irritable bladder, and pain in the ovaries, will assert the same thing, and will diligently hunt for some uterine lesion. If one be found, no matter how trifling, he will attach to it undue importance, and treat it heroically as the erring organ. If no visible or tangible disease of the sexual organs be discoverable, he will lay the blame on the invisible endometrium, or on the unseenble ovaries, and continue the local treatment. In any event, whatever the inlook or the outlook, a local treatment more or less severe is bound to be the issue.

"Yet these very exacting symptoms may be due wholly to nerve strain, or (what is synonymous) to loss of brain control over the lower nerve centers, and not to direct or to reflex action from some supposed uterine disorder. Neither, for the matter of that, may it come from some real, tangible, and visible uterine lesion which positively exists. Thus it happens that a harmless anteflexion, a trifling leucorrheæ, a slight displacement of the womb, a small tear of the cervix, an insignificant

rent of the perinæum, or, what is always present, an ovarian ache, each plays the part of the will-o'-the-wisp to allure the physician from the bottom factor. To these paltry lesions—because they are visible, palpable, and ponderable, and because he has, by education and by tradition, a uterine bias—he attributes all his patient's troubles; whereas a greater and subtler force, the invisible, the impalpable, and the imponderable nervous system, may be the sole delinquent. The sufferer may be a jilted maiden, a bereaved mother, a grieving widow, or a neglected wife, and all her uterine symptoms—yes, every one of them—may be the outcome of her sorrows, and not the outcome of her local lesions. She is suffering from a sore brain, and not from a sore womb. . . .

61

"Strange as it may seem, the coccygeal joint is very liable to play the barometer to any kind of mental worry. The serious surgical blunder is, therefore, not infrequently made of extirpating for sheer hysterical coccygodynia this important bone, important from its muscular origins and insertions. I have known coccygodynia to attack a lady after the death of her mother. Every kind of treatment failed, but it was finally abruptly cured by her great resentment at the second marriage of her father. . . .

"Sometimes in these cases an operation acts the part of an incantation. The dread of the knife, and the shock of the operation, distract the mental attitude of morbid concentration: while the enforced rest in bed gives a chance to the worn-out brain to regain strength, and to assert its supremacy over the mutinous lower nerve centers. This leads me to think that in a large majority of operations upon trifling tears of the cervix, and on incomplete lacerations of the perinæum, the good which may accrue comes less from the repair of those organs than from the mental distraction and the enforced rest. But this kind of incantation-the surgical variety-does not always work well; indeed, it often, very often, makes matters worse One striking example was that of a lady who saw her only child run over and beheaded by a locomotive. Her health began at once to fail, and she took to her back with the hackneyed symptoms of weariness, wakefulness, a bearing down, an irritable bladder, and many other canonical uterine reflexes. These were attributed by an excellent and a conscientious physician to a torn cervix and to a torn perinæum, which were accordingly repaired. But the added shock of the two operations made her very much worse. For these reasons, I must confess to becoming far less inclined than formerly to operate on trifling lesions of the reproductive organs, and especially on small tears of the perinæum, the repair of which is painful, unnerving, and generally of doubtful expediency. I have become very skeptical of the influence of such lesions upon the general health, and have come to the belief that, even in bad cases, it is greatly overrated. In my experience, the mistake usually made in these cases is that of attributing to the lacerations the mock uterine symptoms of nerve prostration. About this there can be no error, for I have over and over again. without any surgical treatment whatever, cured of all their ailments patients who had been sent to me for the very purpose of undergoing some operation on the womb, on the perinæum, or even on the ovaries themselves.

"Just as headache does not necessarily mean brain disease, so ovary-ache, groin-ache, and backache do not necessarily mean ovarian disease. Nerve strain and these aches are, it is true, correlatives, but the middle term which connects them is merely a disturbance in the circulation. Yet time and again—and I say this deliberately—have ladies been sent to me to have their ovaries taken out, when the whole mischief had started from some mental worry. Their ovaries were sound, but their nerves were not, and no operation was needed for

their recovery. The physician of the present day is too apt to jump from any distinctly female ache to an ovarian conclusion without the delay of any misgivings. The ache is in the back, then, he argues, it probably is ovarian; it is in the groin, then, of course, it is ovarian; it is in the head, but extremes meet, and surely it comes from the ovaries. I, indeed, have seen a painful nose, and also a red one, attributed to the ovaries and treated canonically by the hot vaginal douche and uterine applications. From this widespread bias and pernicious haste the removal of the ovaries has degenerated into a busy industry by which, in city and in country, very many women have been and are being mutilated, both needlessly and on the slightest provocation.

"So misleading, indeed, are the symptoms of a jaded brain or of other nerve strain, under the uterine guise in which they often masquerade, that when a jilted girl, a bereaved mother, or a grieving wife consults a physician, he, unless on his guard, will be more likely to minister to a womb diseased than to a mind diseased. Such cases, even when associated with actual uterine disease, are not bettered by a merely local treatment. Nor are medicines by themselves of much avail. What they need are the incantations of the rest cure-viz., massage, electricity, and strict seclusion. Hope should be infused into every case, and, above all, there should be imported into it the personality of the physician. The riper my experience, the more am I convinced that, in the treatment of woman's diseases, the possibility of a nerve origin or of a nerve complication should be the fore-thought and not the hind-thought of the physician."

A Second Laura Bridgman; Helen Keller. - Miss Helen Keller, about whom we have heard from time to time, is now thirteen or fourteen years of age. She became deaf, dumb, and blind in infancy, and yet she has been educated up to such a point that she was enabled, at twelve years of age, to write, by means of her own typewriter, a sketch of her having been led forth from darkness into the light of knowledge. Her sketch is beautifully composed, and is said by the editor of the Youth's Companion, in which paper the composition has been published, to be free from errors of spelling and the like. Her diction is refined and graceful, she makes occasional reference to her readings of the poets, and she is filled with gratitude and lovalty to those who have educated her and taught her to read and write and make use of oral speech. Not only this, but this little lady is engaged in the good work of collecting a fund for the education of an afflicted deaf-mute-Thomas Stringer, of Pittsburgh.

This autobiographical sketch of a rescued intellect may with profit be perused by every physician in the land—we know of no other single profession or walk in life that can more fully appreciate the struggle against and the victory over deaf-mute blindness. The following paragraph, all that we can here quote, recites how this little deaf-mute made the acquaintance of old Neptune. She had probably never before received a particle of harsh treatment; but old Ocean was positively rude. She says:

"Suddenly we stopped, and I knew, without being told, the sea was at my feet. I knew, too, it was immense! awful! and for a moment some of the sunshine seemed to have gone out of the day. But I do not think I was afraid; for later, when I had put on my bathing suit, and the little waves ran up on the beach and kissed my feet, I shouted for joy, and plunged fearlessly into the surf. But, unfortunately, I struck my foot on a rock, and fell forward into the cold water.

"Then a strange, fearful sense of danger terrified me. The salt water filled my eyes and took away my breath, and a grea

wave threw me up on the beach as easily as if I had been a little pebble. For several days after that I was very timid and could hardly be persuaded to go into the water at all; but by degrees my courage returned, and almost before the summer was over I thought it the greatest fun to be tossed about by the sea waves.

"Oh, the happy, happy hours I spent, hunting the wonderful shells! How pretty they were with their lovely, fresh hues and exquisite shapes! And how pleasant it was to sit on the sandy bank and braid the sea grass, while teacher told me stories of the sea and described, in simple words that I could understand, the majestic ocean and the ships that drifted in the distance like white-winged birds!

"People sometimes seem surprised that I love the ocean when I can not see it. But I do not think it is strange. It is because God has planted the love of his wonderful works deep in the hearts of his children, and, whether we see them or not, we feel everywhere their beauty and mystery enfolding us."

She tells in another part of her story of her great grief in the loss, by accidental death, of her pet mastiff, Lioness, but admits that it turned her attention to the doing good to another forlorn deaf-mute blind boy, Thomas Stringer, of Pittsburgh. She made use of the money sent her to buy a new pet to help defray the cost of education, at Mr. Anagnos's school at Boston, of "my little human plantlet," as she styles the adopted boy. This little girl is already worthy to be enrolled in the regiment of philanthropists, although she has only recently entered upon her fourteenth year. It is pleasant to know that her appeals for money for her Stringer fund have met with a loving response from people who have speech and hearing and sight and the ability to earn money.

The Medical Society of the State of New York will hold its eighty-eighth annual meeting in Albany on Tuesday, Wednesday, and Thursday, February 6th, 7th, and 8th, under the presidency of Dr. Herman Bendell, of Albany. The provisional programme includes the following titles: The president's inaugural address; Hæmorrhagic Serous Effusion of the Pleura, with Report of a Unique Case, by Dr. William S. Cheesman, of Auburn; Researches on the Eliminating Power of Diseases, and the Relation between Vaccinia and Enteric Fever, by Dr. William Finder, of Troy; Pneumonia of the Aged, by Dr. John H. Pryor, of Buffalo; The Diagnosis and Nomenclature of Fevers, by Dr. Nelson G. Richmond, of Fredonia; The Therapeutics of Oxygen, by Dr. Arnold W. Catlin, of Brooklyn; Simple Methods in the Diagnosis of Nervous Diseases, by Dr. E. C. Spitzka, of New York; discussion on diphtheria, arranged by Dr. A. Walter Sviter; Pathology-Status Præsens, by Dr. Thomas E. Satterthwaite, of New York; Observations on Diagnosis, and some Sanitary Aspects, by Dr. A. Walter Suiter, of Herkimer; Croup and Diphtheria-Unity or Duality, by Dr. William H. Daly, of Pittsburgh, Pa.; The Comparative Status of Intubation of the Larynx, by Dr. Joseph O'Dwyer, of New York; Complicated Intubation of the Larynx, by Dr. William Hailes, of Albany; The Local Treatment, by Dr. Abraham Jacobi, of New York; The General Treatment, by Dr. Edward F. Brush, of Mount Vernon; The Use of Tartar Emetic in Diphtheria, by Dr. H. DeV. Pratt, of Elmira; The Treatment of Depressions in the Skull of the New-born, by Dr. David D. Jennings, of New York; Immediate Trachelorrhapy, by Dr. Henry C. Coe, of New York; Lymphadenoma of the Uterus, by Dr. H. J. Boldt, of New York; Senile Endometritis, by Dr. A. J. C. Skene, of Brooklyn; The Treatment of Endometritis, by Dr. Herman E. Hayd, of Buffalo; Nine Years' Experience with Alexander's Operation for shortening the Round Ligaments of the Uterus, by Dr. Paul F. Mundé, of New York; Pelvic Ab-

seess, by Dr. Walter B. Chase, of Brooklyn; A Case of Hysterectomy for Retention of the Menses, by Dr. William Gardner, of Montreal; a discussion, arranged by Dr. Andrew F. Currier, of New York, on Menstruation and its Abnormities; Dysmenorrhea-Its Causes and its Treatment, by Dr. Howard Kelly, of Baltimore; Profuse Menstruation, by Dr. Charles P. Noble, of Philadelphia; Scanty Menstruation, by Dr. Franklin Townsend, Jr., of Albany; Irregular Menstruation, by Dr. Charles A. L. Reed, of Cincinnati, and Dr. E. W. Cushing, of Boston; The Menopause-Natural and Artificial, by Dr. Arthur W. Johnstone, of Cincinnati; Urethral Caruncles, by Dr. Edward M. Liell, of New York: The Physical Causes of Sexual Debility in the Male, as distinguished from the Psychical Causes, by Dr. F. R. Sturgis, of New York; The Surgical Treatment of the Prostate Gland, by Dr. Seneca D. Powell, of New York; The Fable of the Egg, by Dr. William S. Ely, of Rochester; Artificial Immunity, by Dr. Henry R. Hopkins, of Buffalo; Clinical Notes on Psoriasis, with Special Reference to its Prognosis and Treatment, by Dr. L. Duncan Bulkley, of New York; Spinal Supports and Braces, by Dr. A. M. Phelps, of New York; The Histology and Pathology of the Spinal Cord, by Dr. William C. Krauss, of Buffalo; a discussion on Abdominal Surgery, by Dr. A. Vander Veer, of Albany; Disputed Points in Pelvic Surgery, by Dr. Joseph Price, of Philadelphia; Influences Affecting the Results of Abdominal Operation, by Dr. J. F. W. Ross, of Toronto, Canada; Hæmorrhage after Abdominal Section-Its place in Statistics, by Dr. A. H. Buckmaster, of New York; Cysts of the Epigastrium, by Dr. Dudley P. Allen, of Cleveland, Obio; The Technique of the Abdominal Incision-Methods of its Closure and its Subsequent Management, by Dr. W. W. Potter, of Buffalo; An Operative Procedure for the Relief of Obstruction of the Common Duct, by Dr. W. E. B. Davis, of Birmingham, Ala.; Two Cholecystotomies for Gallstones, with Recovery, with Remarks on Operative Methods, based upon Five Cases, by Dr. William Wotkyns Seymour, of Troy; Gallstones the Exciting Cause of Malignant Disease, by Dr. Rufus B. Hall, of Cincinnati; Appendicitis, by Dr. Charles McBurney, of New York; An Analysis of One Hundred and Fifty Personally Observed Cases of Appendicitis, by Dr. George Ryerson Fowler, of Brooklyn; A Conservative View of the Treatment of Appendicitis, by Dr. William S. Tremain, of Buffalo; Some Observations Relative to the Treatment of Suppurative Appendicitis, with Report of Cases, by Dr. Willis G. Macdonald, of Albany; Palpation of the Vermiform Appendix, by Dr. J. M. Edebohls, of New York; The Inch-and-a-half Incision and Week-and-a-half Confinement in Appendicitis, by Dr. Robert T. Morris, of New York; Report of a Case of Post-peritoneal Abscess from Duodenal Ulcer, with Presentation of Specimen, by Dr. L. S. Pilcher, of Brooklyn; Intestinal Perforation in Strangulated Hernia, by Dr. William B. DeGarmo, of New York; Remarks on the After-treatment of Abdominal Section, by Dr. Carlton C. Frederick, of Buffalo; The Unexpected as Sometimes Observed in Abdominal Surgery, by Dr. A. Vander Veer, of Albany; Recent Methods of Gastrostomy for Stricture of the Esophagus, by Dr. Willy Meyer, of New York; The Influence of Physiological Rest on Prolapse of the Rectum, by Dr. Joseph D. Bryant, of New York; A Contribution to the Subject of Excision of the Larynx, by Dr. Charles A. Powers, of New York; Observations on One Hundred and Eighteen Cases of Cancer of the Breast, with Special Reference to its Radical Cure by Operation, by Dr. William T. Bull, of New York; The Treatment of Hernia (supplement to a paper read last year), by Dr. Alexander Dallas, of New York; Some Cases of Brain

Surgery, by Dr. Herman Mynter, of Buffalo; The Needlessness

of a Mydriatic in Adjusting Glasses to the Eye, by Dr. D. B. St. John Roosa, of New York; The Action of Scopolamine on the

Eye, by Dr. Thomas R. Pooley, of New York; The Treatment of Nasal Hæmorrhage, by Dr. John O. Roe, of Rochester; Report of a Case of Injury to the Cauda Equina, by Dr. Hermon C. Gordinier, of Troy; The Treatment and Prevention of Epilepsy in the Young, by Dr. Græme M. Hammond, of New York; The Practical Workings of the Law for the Care of the Insane, by Dr. Carlos F. MacDonald, of New York; Lunatics in Public Places, by Dr. Wallace J. Herriman, of Rochester; The Subfrontal Gyre (Broca's Convolution) in Man and Apes, by Dr. Burt G. Wilder, of Ithaca; Acromegaly, by Dr. Floyd S. Crego, of Buffalo; Report of a Case of Acromegaly, with the Exhibition of the Subject, by Dr. Frederick Remington, of Rochester; Uræmic Hemiplegia, by Dr. Reynold W. Wilcox, of New York; and Glycosuria, by Dr. W. B. Vanderpoel, of New York.

Revulsive Treatment.—In the Gazette médicale de Nantes for December 12, 1893, Dr. Bonamy writes substantially as follows: Sad may be the consequences of the skepticism which tends to take possession of the rising generation of medical men as to the value of the old therapeutic agencies. This skepticism, it is true, has raised up a deep faith in the promises of the microbic school, partly pertaining to preventive hygiene, but having more or less connection with the domain of therapeutics. Among the old measures that are accounted as out of date there is one against which a special revolt has been made-namely, the revulsive. Its effects-pain, redness, and cutaneous burningit may be well to ignore, if, as is said in the aphorism by which revulsion is defined: Duobus laboribus simul obortis vehementior obscurat alterum. The author adds that his personal experience in rheumatism warrants him in subscribing to this way of putting it, for he has oftentimes had occasion to regret the application of a mustard plaster to the painful part. On the other hand, he asks, is there not sometimes an advantage in the revulsion produced by eczema supervening in a gouty, asthmatic, or emphysematous subject? He then cites Professor Brocq, the dermatologist, asaffirming that by treating eczema too energetically we may bring about the most serious pulmonary or cerebral congestion. May not this same thing happen, he asks, if we arrest too suddenly the eruptions of lichen or impetigo, which, according to Vogel, that sagacious observer of infantile diseases, make their appearance with the first tooth, are somewhat persistent, and disappear only to appear again at the time of a fresh eruption of teeth? The author says that he has seen fatal accidents follow very closely upon retrocession of these rashes in infancy. So much, he says, for pathological revulsion; as regards therapeutic revulsives, especially the blister, how, he asks, can we disregard the testimony of Bouillaud, renowned for his minute exactness in the observation of facts, when he declares that he would rather disbelieve that it was daylight at noon than distrust the efficacy of blisters in acute diseases of the chest? Does not congestion always exist, the author asks, more or less pronounced, at the situation of the hepatized areas. and may we not repeat, with some reason, what Peter said of tuberculosis of the same organ: "Congestion, then, is the enemy; and one of the best weapons against it is the blister"? He goes on to say that the usefulness of blisters has appeared to him certain in the course of recent epidemics of influenza complicated with broncho-pneumonia of a hæmorrhagic character. He then quotes from Maurice Raynaud as follows: "Should we not be violating all the rules of philosophical induction if we were to admit, as everybody now admits, that an impression of cold on the skin might give rise to a visceral congestion, and at the same time deny that a different impression upon the point of the cutaneous envelope could in turn produce an effect the reverse of the first?" Further proof is furnished by the results of experimentation. Zuelzer, cited by Guès (Jaccoud's Diction-

naire), applied cantharidal preparations for several days to the back of various mammals; he then killed the animals and found hyperæmia of the skin and of the superficial muscles, accompanied by the reverse condition of the corresponding deep parts. This, says the author, must necessarily be. It is clear that, if the blood flows into a certain portion of the skin, anæmia must at the same time be produced in the subjacent parts that are in nervous or vascular communication with it. It is even demonstrated physiologically that the anæmia will be more decided accordingly as these parts were previously more congested. Thus, especially in pleurisy, is explained the efficacy of blistering, the effects of which, hyperæmia and exudation, are so closely allied to the pathological process on the pleura. Of late years a notable increase in the mortality from pleurisy has been observed, and that in spite of the current practice of thoracocentesis. Undoubtedly, the author thinks, blisters have not been used enough. The possibility of consecutive albuminuria has been urged as an objection to their employment. But, he asks, is the transitory albuminuria more to be dreaded than that which is occasioned by eating too many eggs? Moreover, have we not the alkaline treatment to prevent it? Of course, the author adds, blisters must not be used in cases of diabetes or diphtheria. In conclusion, the author calls attention to Professor Potain's advice to apply a blister over the course of the pneumogastric nerve for vomiting produced by compression of this nerve in cases of tuberculosis.

### Unusual Symptoms of Poisoning with Carbon Dioxide.-

The Revue générale de médecine, de chirurgie et d'obstètrique for December 13, 1803, publishes an abstract of an article by Dr. R. Kayser, which appeared in the Wiener medicinische Wochenschrift, 1893, No. 41, in which there is related the case of a woman, thirty-six years old, who tried to commit suicide by inhaling the vapor of burning charcoal. When she came out of the coma produced by this attempt at poisoning she complained of violent tinnitus aurium and of complete deafness. Moreover, she showed psychical excitation, was maniacal, and was the victim of ballucinations of hearing. These abnormities disappeared, save the deafness and the tinnitus aurium, which still persisted at the time of her leaving the hospital, four weeks after her entrance. Nothing abnormal was ascertained on physical examination of the ears. The hearing power for the lower notes of the gamut was preserved. Faradization of the head was followed by very distinct amelioration. The author was inclined to think that the disorders noted in this case, in so far as concerned the hearing, were connected with hæmorrhagic lesions of the ear.

At a recent meeting of the Paris Société de biologie, the proceedings of which are reported in the Union médicale for December 16, 1893, M. Hallopeau said that he had witnessed in a patient poisoned with carbon dioxide convulsive tremor of the limbs, manifesting itself exclusively at the close of each respiratory movement and being reproduced with absolute rhythm, The inference was that the failure of adequate hæmustosis had been sufficient to produce excitation of the motor convolutions.

Phulluah as a Remedy for Hemiplegia.—In the Indian Medical Record for November 16, 1893, Mr. E. C. Beddell, W. M. O., relates the case of a Hindu, forty-two years old, who in his youth had been a sepoy in a rajah's service and had received a sword wound and two bullet wounds. The scars of these wounds were still to be seen, but their situation could in no way account for his paralysis. He had always enjoyed good health and had never had a head injury, a sunstroke, or a fit of any kind..—His story of his paralysis was as follows: One night he had gone to sleep perfectly well, and the next morning been

found insensible. On recovering consciousness, he had found himself in a hemiplegic condition. For fifty-four days thereafter he had been unable to walk and had had great difficulty in swallowing. He had gradually recovered to some extent. He had for a long time been under "hakimi" treatment [whatever that might bel, but had not been benefited by it. On inspection, the author found the man's right side paralyzed. His tongue, which was moist and clean, was protruded toward the paralyzed side. His sensibility was partially affected; he could not tell accurately the situation of a part touched. There was a slight trace of sensation in the occipito-frontalis, the right masseter, the biceps, and the triceps, but it was quite lost in the right trapezius, the rectus, the vastus internus, and the hamstring muscles. The patient could lift his hand to an angle of about forty-five degrees. The usual routine treatment could not be carried out for want of proper medicines and appliances, and the author was therefore obliged to adopt such measures as were within the patient's means. His bowels were cleared out with calomel, and it was ordered that a liniment of eight ounces of phulluah, two ounces of oil of turpentine, and four ounces of rum should be rubbed into the affected parts three times a day. Continued friction with this liniment, together with steady massage, caused a remarkable improvement, and the patient was able to lift a weight of three pounds and three quarters with the paralyzed hand after a month of such treatment. The author is inclined to attribute the favorable result to the use of phulluah and massage. Phulluah, he says, is an oily substance obtained from a plant that grows wild on the hills about Nani Tal. In its fresh state it resembles small white balls of about the size of areca nuts. It melts on exposure to heat. When kept for some time in its liquid form, it becomes of a dirtybrown color. It is largely used among the tribes of the hills for the cure of frostbites and chilblains. The author has found the topical use of phulluah very beneficial in rheumatism, sprains, sciatica, and chilblains, and he is inclined to think that it would do good service in cases of gout, but as yet he has not had the opportunity of giving it a trial. He adds that it has never failed to produce the desired effect where other local applications have been practically valueless. Its action seems to him to be stimulant, emollient, powerfully anodyne, and antiseptic. It is best to heat the crude drug and then use it like an ordinary liniment by friction.

The Rush Medical College, Chicago.—The registrar has issued the following circular, dated January 10, 1894: "In pursuance of the policy recently announced in the resolution to be presented to the American Medical College Association, the trustees and faculty of Rush Medical College have decided to require four years' attendance at college from students who begin the study of medicine this year with a view to graduation in 1898; however, those who have already studied medicine one year or more with a preceptor, so that the four years of study already required will be completed before July, 1897, may graduate after three courses of lectures, as heretofore. To encourage proper preliminary study, graduates in arts and sciences from high-grade colleges and graduates in pharmacy and dentistry from colleges requiring a proper amount of study and two full courses of lectures will, until further notice, be allowed to graduate after an attendance on only three courses of lectures."

Dr. Sachs's Article on Syphilis and Tabes Dorsualis.— The author asks us to state that in Figs. 1 and 2 of the plate accompanying his article, published in the *Journal* for January 6th, the lateral and antero-lateral regions are of a lighter color than in the original drawing. This, he says, does not represent a diffuse sclerosis, for that was limited to the posterior columns.

OBSCURE INJURIES OF THE SPINE
FOLLOWED BY PARALYSIS OF LONG STANDING,
RELIEVED BY SUSPENSION AND PLASTER-OF-PARIS JACKET.\*
BY LEWIS A. SAYRE, M.D.

HAVING seen a number of cases of serious injury of the spine followed by paralysis, more or less complete, involving the bladder and rectum, which were relieved by suspension and a plaster-of-Paris jacket, and eventually entirely recovered, and two of these patients having recently called upon me in perfect health after the lapse of many years, it occurred to me that it would be desirable to look over my note-books, and publish the records of the cases for the benefit of the profession.

Case I .- C. W. H., about thirty six years of age. On October 15, 1877, in switching from a main track to a branch, the train going around a curve at a rapid rate, while he was standing in the rear of the car, he was violently thrown upon the corner of a stove and instantly paralyzed below the waist, probably by a fracture of one of the lumbar vertebræ, presumably the third. While paralysis of motion was complete at the time, there was some sensation and pain in the outside of the left thigh for a few bours. There was loss of control of the bladder and rectum, with a feeling of constriction, as of a tight band, about the lower part of the abdomen, the line of demarcation between the active and paralyzed parts being clearly defined. Pain at the point of injury was incessant and severe beyond description. The bowels were evacuated by cathartics and clysters, and the bladder by the catheter. After ten weeks there was some return of sensation with ability to evacuate the bladder voluntarily as a general thing, and in a little more than five months from the time of the injury there commenced a slight muscular action in the legs, which increased irregularly, so that in a year after the hurt the limbs could be drawn up and pushed down in the bed, and even be made to move as in walking, with the body supported on crutches and by an attendant, but only a trifling amount of weight could be sustained by them.

During all this time there were frequent periods of almost total paralysis of both motion and sensation, greatly influenced evidently by the formation of numerous abscesses, which began about six months after the injury, discharging through the rectum, the outside of the right thigh, and the inside of the left. the latter giving exit to two fragments of bone half an inch to an inch or more in length and from one to two lines in thickness; one piece from two or three lines in width at the base, tapering to a point, and partly necrosed; the other, from one to two lines wide, somewhat pointed, and slightly curved or twisted in shape, but perfectly bright and clean, and showing its fracture very plainly. The patient, who was a physician, stated that he was confident that another fragment of bone had previou-ly escaped per rectum, while still another was distinctly felt in the abscess that formed in the outside of the right thigh, but afterward disappeared. During the winter of 1878-'79 abscesses formed with great frequency, causing much loss of strength through the large quantities of pus formed and the

The abscesses finally stopped forming under the use of iodide of potassium, so that after May, 1879, only two appeared, the last about the 1st of August. With the cessation of the abscesses improvement took place in the general health and in the action of the legs, apparently aided by the daily use of electricity and frictions and the persistent exercise of the muscles by volition, so that by the autumn of 1879 he was able. at times, to get a part of his weight on his feet by supporting himself on crutches or over the back of the chair. But he was still unable to be off the bed except for a short time during the day, and often he did not even make the pretense of sitting up for more than a week at a time. He was compelled to evacuate the bowels by injections, except at times when suffering from painful diarrhea. He also suffered such intense pain in his spine and limbs all the time that he was forced to take from one to three grains of morphine daily to keep even bearably comfortable.

On November 30, 1879, the actual cautery having previously been applied with but trifling benefit, if any, with the assistance of my son, Dr. L. H. Sayre, I suspended the patient, and encased him in a plaster of-Paris jacket. The relief from pain, and the improvement in the sensation and motion of the limbs thus produced, indicated the probable benefit which would follow from this mode of treatment.

The jacket was applied exactly as described in my work on Spinal Disease and Spinal Curvature, etc., the closest attention being given to the minutest details. The result was a remarkably accurately fitting case which gave perfect and even support to the whole trunk, and complete and absolute rest to the injured and diseased parts. Three days later the patient could walk about the room without mechanical support, and two days after this he went on the street for his first walk in more than two years. Sensation, which had been very imperfect, became nearly normal; control of the muscles became constant and much more perfect; the frequent attacks of spasmodic contractions of groups of muscles entirely ceased, as did also the occurrences of almost total paralysis of the legs, during which he would often be unable to draw them up in bed for days at a time. Complete control of the bladder was obtained, and the bowels became much more natural in their action, enabling him to wholly discard injections. He was also enabled to discontinue the use of heat to the limbs, as they had become as warm as the other parts of his body. Though still suffering severe pain at the point of injury, he succeeded, within a period of six weeks, in reducing the quantity of morphine to less than one half of that taken before the jacket was applied. At this time the muscles were still too weak to sustain the weight of the body with the legs flexed, or to raise it on the ball of the foot and propel it forward as in natural locomotion. This gave him a necessarily slow and somewhat awkward movement, but there was apparently no paralysis of any muscle at this time, and he was able to walk a fourth of a mile without artificial aid of any kind, except the moral support of a light bamboo cane.

On removing the jacket, January 13, 1880, he found himself unable to walk across the room without support of some kind, while there was a marked increase of pain. There was also a

severe pain they created. The partial recovery of the action of the muscles was in a great measure lost, so that they responded to the test of electricity no more than would those of a man recently deceased, and he was unable to distinguish the difference between heat and cold when applied to the surface of the extremities; indeed, so imperfect was sensation that both legs were badly burned on different occasions by too hot soapstones, it being necessary to use artificial heat to maintain the proper warmth in the extremities.

<sup>\*</sup> Read by title before the Section in General Surgery of the First Pan-American Medical Congress.

perceptible change in the form of the trunk, it being two inches smaller around the waist, probably by absorption from lateral pressure of the jacket above the lila, where it had been crowded in to get a point of support to maintain extension. Upon the application of a new plaster case there was immediate relief of the increased pain and a return of the use of the legs as before, with considerable improvement in their action, the new jacket being, if possible, a better fit than the first. This showed most clearly the need of and the great benefit derived from the extension and support of the plaster jacket.

On February 1st he reported that he could then raise himself on his toes by voluntary contraction of the extensor muscles of the feet.

On March 11, 1880, he called at my office feeling perfectly comfortable. He could walk without cane or other support nearly as well as before the accident. He wore the jacket eighteen months, when he was perfectly consolidated. Since then he engaged in the active practice of his profession until July, 1887, when he died.

Case II .- W. F. C., twenty-nine years of age, was brought to me by the preceding patient, both of them having been injured by an accident on the same railroad. On August 10, 1877, while acting as mail agent, he was in a train which ran off the track and for some distance on the ties, during which time Mr. C. was thrown violently about the car in various di. rections. This caused partial loss of consciousness for a short time. He was soon, however, in the possession of his faculties and continued at his duties as mail agent until August 13th. During these three days he suffered severe pain in the lumbar region, where there was noticed a slight swelling and contusion. Four days after the accident he gave up work and took to his bed, on account of severe pain in his loins. His bowels had been constipated for three days following the accident, and he had also experienced considerable pain in his head during this time. On the third day the patient for the first time was unable to voluntarily empty his bladder, except while supporting himself by his hands on the arms of a chair, or by supporting himself on crutches. This continued up to the time he was first seen by me-January 17, 1880. He was confined to bed for twentytwo months, continuously so for thirteen months, with occasional intermissions of a few moments at a time. Three weeks after receiving the injury he noticed loss of sensibility in both feet, which gradually increased, and extended upward until it reached the knees, which was at the end of ten months. The anæsthesia now gradually subsided from the right leg, while it extended upward in the left, involving the whole thigh. During these ten months he was actively treated-local bleeding by means of leeches, blistering, iodide and bromide of potassium in full doses being used. The loss of sensation in the left limb remained unchanged until July, 1879, when he felt sharp pain from the back pass down the inside of the thigh and leg, and while before July, 1879, pricking with needles or the application of a strong current of electricity failed to cause any sensation whatever, he now began to feel a tingling from such operations. Voluntary motion in the left limb became impaired from the first, and at the end of seven months was completely abolished. Voluntary motion in the right leg was never impaired. There had been a total loss of sexual power from the first, though sensation of the genitals had been normal. The pain in the lumbar region was continuous and severe for thirteen months from the time of the injury, but it then began to diminish and had gradually grown less severe. During these thirteen months the patient was actively treated as before described, and a brace was employed; but, owing to the continuous and severe pressure which it caused on the crests of the ilia and under the arms, it had to be discontinued. During this

time he had been seen by a large number of distinguished physicians in different parts of the country, all of whom considered his case incurable, but thought he might receive some relief

At the time when he first came under my observation, January 17, 1880, the patient weighed about two hundred pounds, very nearly what he weighed before his injury. His appetite and digestion were good and the bowels were regular. He slept tolerably well. The right limb was normal, the left incapable of any voluntary motion. There was some sensation in the limb, so that when a needle was plunged into the patient, be experienced a sensation as though his leg had "gone to sleep." The limb was well nourished, having diminished but little in size. There was constant pain in the back, though not very severe. Pressure over the first and second lumbar vertebræ caused an increase in the pain; crowding the vertebræ together by pressing on the head or shoulders increased the pain in the lumbar region, while when the superimposed weight was taken off by suspending the body by the shoulders, the patient felt perfectly easy. He was unable to sit erect longer than fifteen or twenty minutes without its causing violent pain and great exhaustion. When he supported himself on his crutches he felt very comfortable and could remain so for an hour or more. The urine could not be voided except when the patient suspended his body from his shoulders by means of his arms or hung upon his crutches.

January 18th.—He was to-day cupped over the lumbar region and about four ounces of blood obtained, deep punctures by means of a sharp tenotome being employed instead of scarification.

January 23d.—Sensibility of the left limb has increased since the cupping, and the pain on pressure in the lumbar region has diminished. The actual cautery was applied on each side of the lumbar spine, over the transverse processes, for about three inches.

February 3d.—Suspended the patient and applied a plasterof-Paris jacket. When it had set he could stand without other support, which he had not been able to do since the accident. Sensation has returned to the left leg since the application of the cautery, and he can now slightly move the toes voluntarily.

March 16th.—A letter was received in which the patient said: "Sensibility and motion are returning rapidly; the former is now nearly perfect. All the muscles now respond to the battery."

May 26th.—Patient returned. Sensation and motion greatly improved. He can now walk with the assistance of a cane. The jacket was removed and made into a corset. There was no tenderness on concussion or pressure along the spine. He could stand erect without any support.

September 20th.—He has been in perfect condition since the last note; he can now stand without pain or support.

March 23, 1881.—Mr. C. returned to-day in apparently perfect health, but he states that he can not yet do without the corset for any length of time. In December, 1880, he first attempted to do without it, and he became much exhausted after a few moments. He has, however, gradually increased in strength, so that he can now leave it off for a whole day, provided he does not walk or exert himself. The genital organs still remain powerless—no sexual desire or erection. He can pass his water easily when the jacket is off.

November 9th.—He returned in perfect health except as regards his sexual organs. He has not worn the jacket since last July.

June 26, 1886.—Patient looks perfectly well; weighs two hundred and five pounds; says he can not lift any weight without feeling it in the back. The numbness in the feet has en-

tirely disappeared; sexual power has returned, but there is no desire.

August 2, 1803.—The patient called to see me as he was passing through town with his wife and three-year-old boy. He was in perfect health, sexually as well as otherwise. He frequently rides sixty miles a day on horseback without suffering any pain or fatigue.

Case III.—Mr. O. E. B., aged fifty-three years, in June, 1879, was standing up in the rear car of a train when it jumped the track and ran on the ties for some distance and then turned over. When he was removed from the wreck he had severe pain in the lower part of his back and no sensation in his lower extremities. The lower extremities were entirely motionless and cold. The right external malleolus was torn off and he received various other bruises about the body. The bladder failed in its functions after the accident, and the urine had to be withdrawn by catheter. The bowels became costive and required to be moved by cathartics. Digestion remained good and appetite fair. It was supposed by his medical attendants at that time that there had been a dislocation of the eighth or ninth dorsal vertebra which was pressing on the cord.

He suffered great pain and loss of sleep. On the fourth day sensation began to reappear in the lower extremities, and this soon developed into a hyperæsthesia. This hyperæsthesia also affected the upper part of the body. He did not suffer from severe pain in the spine at this time. After the tenth day the bladder resumed its function. On the third or fourth day, after many trials, he succeeded in moving the second too of his left foot slightly, and from this time motion gradually, but very slowly, developed in other parts of his lower extremities, and in the course of a few weeks he could extend the leg a little upon the thigh. A slight slough occurred on the left heel. The lower extremities remained very cold, and had to be kept warm by hot bottles and the use of friction, etc.

In September he first rode out in a carriage, but while riding could not be comfortable except when supporting himself on his arms, and each time when he came home he felt so very tired and exhausted that he was finally obliged to give up this exercise.

On October 30th a felt corset was applied to him. This made him feel much better, and gave support to his back. With this on he again rode out and with more comfort. The right foot and leg remained somewhat painful. The right thigh was atrophied, measuring an inch and a half less than its fellow.

In the latter part of December he began to bear some weight upon his legs, and could, when first seen by me in March, 1880, bear his whole weight on his limbs after he had been helped to the upright position. While sitting up he had a frequent desire to raise himself upon his arms. He could flex the thighs moderately, and the legs upon the thighs. The left leg had more power than the right.

The tenth and eleventh dorsal vertebræ were more prominent than the others. The spinous and transverse processes were more prominent and much thickened, and on firm pressure considerable pain was produced. Below this point there was more than the ordinary lumbar lordosis. Sensation was still a trifle exaggerated below the tenth and eleventh dorsal vertebræ, except in the left foot, where there was partial anæsthesia. On touching the sole of the right foot an immediate reflex muscular movement followed, while in the left reflex movement was considerably delayed, and the foot then moved very slowly. When sitting up for any length of time he supported himself by leaning on his arms, which, he said, "rested him." He had to be assisted to his feet, after which he could stand by supporting himself somewhat on his crutches. By being raised so as to take most of his weight from his feet, he

felt better than when standing. After being supported in this way for some moments he felt, when let down again, tender and uncomfortable along the lower part of his back.

About five or six ounces of blood were drawn from the lower dorsal region by means of deep incisions and cupping glasses.\* The next day the patient voluntarily remarked that his thighs felt different, and that he could move these muscles voluntarily, which he had not been able to do since the accident. The actual cautery was applied on the right side, opposite the tenth dorsal vertebra, and on the left side, opposite the fourth lumbar vertebra. When the burns of the cautery had healed, a plasterof-Paris jacket was applied, from which he experienced some relief from the constant aching in his back, but not complete freedom from pain. He was able to move his extremities more freely, but the jacket did not give him the expected and desired relief to his pain and improvement in muscular strength, and it was evident that too much "dinner pad" had been used, and sufficient "waist" had not been made to the jacket. This jacket had been applied while he was sitting on a stool and partially suspended from his head and axillæ. A second jacket was applied while the patient was suspended from his head and arms while standing upright, the extension being carried to the point of making the patient comfortable. Great care was used in "waisting in" the jacket, and in this better-fitting jacket he had but little pain in his back and was able to walk very much better. He said it gave him great support.

Six months later he wrote that he was improving surely but, as he thought, very slowly. The right leg continued to be an inch and a half smaller than the left, and had much less power, although it could bear the whole weight of his body. The left leg was strong but sluggish. The circulation continued to be slow in both lower extremities. He used his crutches in going outdoors, but in the house he could get about with two canes, and could take a few steps without support. He also thought he had improved more in the last four weeks than in the preceding few months.

In December, 1881, he called on his way to Europe; walked upstairs without assistance except his cane, and his hand on the baluster. He could walk on the level ground without jacket or support, and could concuss himself on his heels without pain, but preferred to wear the plaster jacket for protection. He could cross each leg over the other, but did this better with the left than with the right; he had voluntary control over the muscles of his lower extremities. The left leg is more tardy in its movements, although it is the largest. A plaster-of-Paris jacket was applied and made into a corset, and with this he sailed for Europe.

In 1887 he reported that he had steadily improved, although his legs were still slow in responding to his will. He was still using massage and Swedish movements.

In February, 1892, he called, and stated that he had been able for some years to walk up and down stairs without assistance, and was in perfect health and attending to active business, but was unable while lying down to rise from the floor without assistance.

The patient was seen in June, 1893, and his back continued well,

CASE IV.—L. V. T., about twenty-eight years of age. While he was in charge of an express cr., in May, 1886, the train was derailed and fell down an embankment ninety or a hundred feet into Lake Champlain, the car turning over several times, and

<sup>\*</sup> In all of these cases the blood was withdrawn from punctures made very deeply along the spine, and not from superficial scarification—a point which, I think, is of much importance in cases of congestion of the spinal cord.

the iron safe striking the patient violently a number of times. He was rendered partly unconscious by the fall, and when he came to himself was unable to move his lower extremities. He has had very defective control of his bladder and bowels since the time of the injury.

When first seen by me, some months after the injury, he was still paralyzed as to motion and sensation in the lower extremities, bladder, and rectum, but not completely so, as he was able to drag himself about on crutches but was unable to rise without assistance. He had severe pain in the lumbar region, and the sensation as of a girdle around the waist. While partly suspended by the head and shoulders, he could move his legs with greater ease and the girdle sensation disappeared, and with a plaster jacket could sit upright for several hours without discomfort. When unsupported by the jacket he had constant pain in his back, and was unable to sit erect for more than a few moments. Plaster jackets, applied while the patient was partly suspended by the head and shoulders, were renewed at intervals of about six months for a period of two years. The patient recovered control of his bladder and rectum in about eight months, was able to walk with the aid of a cane in about eighteen months, and at the end of two years and a half was perfectly well. On applying to the express company for information as to his present condition, I received a reply on August 21, 1893, saying: "Mr. T., referred to in inclosed correspondence, is to all appearances in perfect health."

There are certain points of similarity in all these cases upon which I wish to dwell with especial emphasis. They all of them remained more or less completely paralyzed for long periods after the receipt of the injury-in one case over two years-and marked improvement did not begin until traction was made on the spinal column. In every case when the spine was stretched the patients said they felt better; they had more control of their limbs, and sensation was keener. In one case the patient was unable to evacuate the bowels or bladder except when the superincumbent weight of the body was lifted off. All these cases continued to feel this improvement so long as they were properly sustained by properly fitting plaster jackets. When the support became broken down and failed to retain the spine in its stretched position, the symptoms began to return, to disappear again on the reapplication of the stretching and retention of the spine in this position by an accurately adjusted support.

#### A CASE OF

CONTUSION AND RUPTURE OF THE ILEUM WITH PERITONITIS, WITHOUT EXTERNAL WOUND, SUCCESSFULLY TREATED BY

CŒLIOTOMY AND PRIMARY ENTERECTOMY, FOLLOWED BY CIRCULAR ENTERORRHAPHY (MAUNSELL'S METHOD). EXHIBITION OF PATIENT AND SPECIMEN.\*

BY FREDERICK HOLME WIGGIN, M. D.,
PRESIDENT OF THE SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL;
VISITING SURGEON TO THE CITY HOSPITAL (LATE (HARITY), ETC.

The case which I desire to call your attention to this evening presents several features of interest, and some important points for reflection and discussion. The surgeon

is beginning to invade, and successfully, the field which to within a short time the physician has considered entirely his own—namely, peritonitis without external evidence of injury. Cases of this nature that have been treated by coliotomy and intestinal suture, in which recovery has followed, have been few. A careful search of the literature discloses only one recorded case of successful primary resection \* in this class of injuries, exclusive of the one I am about to bring to your notice.

That injuries of this nature are not of great rarity is admitted as soon as the variety of accidents that lead to this condition is considered—e. g., kicks, blows, falls, etc.; nor are they confined to any locality or any special walk of life. That this is true is proved by the fact that in the course of my private practice I have had two cases within twenty-eight months-one in May, 1891, and the other in September of this year. It is a group of cases that will be more carefully considered hereafter, and must be of great interest to the general practitioner, as from the absence of external wound he will be first called to such a case. On him, therefore, in the future, will the responsibility largely rest for the failure of surgical aid to end in recovery of the patient. This my cases exemplify, and the mere statement of the facts in each answers the question, Why did one patient die while the other recovered?

Case I .- Late on the evening of May 28, 1891, I was called in consultation to see H. W., fourteen years of age, whose physician gave me the following history: On the afternoon of the 23d, while feeding a calf, the boy received a kick in the right lumbar region. The pain, which was at first severe, soon passed away, and he went on with his regular vocation, not even mentioning to his family the accident that had befallen him. The following day (the 24th) being Sunday, he attended church after doing his chores as usual, and went again in the evening. While at this service, he was suddenly seized with violent colicky pains, nausea, and vomiting. On the 25th the family physician was sent for. His attention was not at first called to the accident, and the patient complaining of constipation with the other symptoms, he was given large doses of magnesium sulphate, enemata, and morphine in constantly increasing doses. Bran poultices were applied externally.

As the patient steadily grew worse under this treatment, five days after the accident I was sent for. On examination, no external marks of violence were found. The abdomen was tympanitic; muscular rigidity was marked and increased by pressure, and especially at a point two inches to the right of the umbilious. There was slight dullness on percussion at this point. The general abdominal pain had disappeared, vomiting had ceased, and constipation was absolute. His countenance was drawn and anxious; the temperature was 99.5°, pulse 130, and respirations 30.

The diagnosis was intestinal rupture and general suppurative peritonitis. Although the prognosis was very unfavorable. I advised operation as the patient's only chance. Cediotomy confirmed the diagnosis. A large amount of pus was found in the cavity, shut off at various points by adhesions, and a rupture of the ileum, which was closed by Lembert sutures. The general cavity was washed out with a weak solution of hydrogen dioxide, the external wound partially closed, and drainage with jodoform gauze employed.

<sup>\*</sup> Read before the Society of the Alumni of Bellevue Hospital, November 1, 1893. For a report of the discussion, see vol. lviii, page 700.

<sup>\*</sup> Croft, Clinical Society, London, March 14, 1890.

The anæsthesia was badly borne; the patient stopped breathing and was revived with much difficulty during the operation. The operation was prolonged by the great intestinal distention, necessitating several incisions to allow gas and fæcal matter to escape before they could be returned. The patient died six hours after the completion of the operation, which occupied two hours.

The chief points of interest in this case are: (1) The absence of shock; (2) the cessation of pain for twenty-four hours after the accident, although the intestine was so badly contused that it then became perforated; (3) the energetic medical treatment employed for three days and the consequent delay before surgical interference was considered; and (4) the length of time required for the operation.

Case II.—On the evening of September 11, 1893, I was called to see A. M., fifteen years of age, a colored boy. He gave the following history: On the afternoon of the same day, while in a pasture, he had received a kick from a horse on the right lumbar region and right elbow. He was found lying on his stomach, groaning. In about ten minutes he began vemiting, and complained of continuous nausea. At first he vomited only food, but later, both before being moved and after, he vomited each time about four ounces of dark, clotted blood.

On examination at 8.30 p. m., the patient was found to be suffering slightly from shock. He lay on his back with his knees drawn up, and he complained of great pain, especially at a point to the right of the umbilious. There were no marks of external violence on the abdomen. He had an anxious expression. Morphine, an eighth of a grain, was administered hypodermically, and a drachm of fluid extract of ergot was given by month. An ice bag was applied locally. At this time his temperature was normal and his pulse 80.

September 12th.—The pain continued all night, at 2 a. m. his pulse was 104 and temperature 100.5°, and soon after 3 a. m. another hæmorrhage through the stomach occurred, about eight ounces of dark, clotted blood being ejected. This was repeated at 9 a. m., his pulse at this time being 106 and his temperature 101°. Owing to a misunderstanding, I did not see the patient again until 7 p. m., when his condition was as follows: Pulse, 114; respirations, 30; temperature, 102.5°; he was lying on his back with his knees drawn up, and with an anxious countenance. The abdomen was tympanitic; there was marked muscular rigidity, increased by pressure at the point of greatest tenderness—i.e., to the right of the umbilicus.

The diagnosis was traumatic peritonitis with contusion and perforation of the intestine, and an immediate operation was advised. To this the patient consented, and at midnight, with the able assistance of Dr. W. S. McLaren, of Litchfield, Conn., to whom I wish to acknowledge my indebtedness, the operation was performed. Just previous to the administration of the ether his temperature was 102.7°, pulse 116, and respirations 33.

An incision about four inches long, in the median line between the umbilicus and pubes, was made and the peritonæum opened. The transverse and descending colon were filled with hard fæcal matter, owing to the fact that the patient had a large condyloma which unade defecation painful. Beginning at the cæcum, the small intestine was drawn out of the cavity and carefully examined inch by inch. It was more or less distended, and there was a fibrinous exudation and also slight adhesions, especially about the injured knuckle. A knuckle of intestine was soon discovered, which was ecchymosed, but only near its mesenteric border. It was decided, after careful consideration, that this portion would recover its circulation and

tone, and it was passed by. On going higher up, near the jejunum, another knuckle of ileum was found, which was so bruised and dark in color that, although no perforation could be discovered prior to removal, it was thought best to excise about six inches. (After removal, a small perforation was found at about the center of the specimen, near its mescnteric border.

This was done, safety-pins being used for clamps. The vessels in the cut mesentery were ligated separately, and the edges of the mesentery united by a continuous suture of catgut. The healthy ends of the ileum were brought together, invaginated, and united by Maunsell's method, except that the sutured ends of the bowel and the longitudinal slit in the gut were not painted with Woelfler's solution, nor were the raw parts blown over with iodoform, as advised by him.\*

While the ileum was being excised the patient came out from the influence of the ether, strained and tried to vomit, and a quantity of blood and fæcal matter escaped into the peritoneal cavity. This accident was due to the large size of the safetypins. A liberal quantity of a fifteen-volume solution of hydrogen dioxide was poured into the cavity, and allowed to remain while the ends were completely joined, when more hydrogen dioxide was poured over them. Some time was allowed to elapse before the resulting foam was washed off and the cavity flushed with normal sterilized salt solution (0.6 per cent.). Then the intestines were returned to the cavity, which was freely irrigated and left full of hot sterilized salt solution. The wound was closed, no drainage being employed. The operation from the time of beginning the anæsthesia occupied an hour and a half, and was concluded at 1.30 A. M.

13th.—At 4 a. m. the patient's pulse had risen to 130, and the temperature had fallen to 99.5°. During the night there was very little nausea. At 10 a. m. his pulse was 114, temperature 102.4°; and at 9 p. m. the pulse was 136 and temperature 102.2°. Morphine was given in one-eighth-grain doses every three hours, beginning at 4 p. m. At 11 p. m. he was comfortable and retained peptonized milk.

14th.—At 2 A.M. his pulse was 118 and temperature 100°. At this time gas escaped from the rectum (twenty-four hours

<sup>\*</sup> Am. Jour. of the Med. Sciences, March, 1892.

and a half after the operation). The patient slept well, retained peptonized milk and beef peptonoids during the day, and complained of no pain. Gas was freely passed from the rectumand he had a desire to have a movement. At 8 P.M. his pulse was 104 and his temperature 101°.

There is little of further interest to report. The patient's bowels moved without aid on September 15th at 2 P. M. (sixtyone hours and a half after the operation). During the ensuing twenty-four hours (September 16th) the patient had five large movements, and the morphine was stopped. On September 17th the patient had five movements. He had complained of no pain. His pulse was 98 and his temperature 99 5°. After this the temperature and pulse became normal and remained so. The bowels moved every day or every other day without aid, and on September 21st he was allowed ordinary diet. He has remained in good health, and now awaits your inspection.

The points of interest in this case, aside from its successful termination, are: (1) The hæmorrhages, which in recorded cases, successful and unsuccessful, that I have found, occurred only once-in Croft's case, and this was very slight; (2) the slight amount of shock when the patient was first seen, four hours after the accident, the temperature and pulse being normal; (3) the excision of the contused and perforated portion of the ileum, and the end-to-end union by Maunsell's method, which is comparatively new, and has not been employed many times; (4) the use of hydrogen dioxide in full medicinal strength for the purpose of disinfecting the general peritoneal cavity, this being the second successful case in which it has been used, the other being one of my own a few days previously; (5) the closing of the abdominal wound, leaving the peritoneal cavity full of hot, sterilized salt solution, the object of this being to lessen shock, to prevent adhesions, to aid in the readjustment of the intestines and omentum to their proper positions, to lessen the danger of septic peritonitis,\* and to aid by osmosis the action of the bowels; (6) the shorter duration of the operation; and (7) in the after-treatment the early administration of peptonized food,

In the first case the operation was performed after five days' delay, having thereby been rendered more difficult, and requiring prolonged anæsthesia, which the large doses of morphine rendered more dangerous. The patient was exhausted from pain, constant nausea, and want of proper nourishment, and was septic. In the second, the early recognition of the condition, the comparative promptness with which the operation followed, its shorter duration, the use of hydrogen dioxide in full strength, the filling and closing of the peritoneal cavity with hot sterilized salt solution, made the difference between failure and success.

A careful study of all the recorded cases, successful and unsuccessful, and my own, shows the causes of failure of surgical measures to be (1) delay, which has been responsible for by far the greatest number of deaths; (2) hæmorrhage; (3) failure of the suture and septic peritonitis.

Delay must be obviated by a fuller knowledge of the meaning of the symptoms by the general practitioner. The important factors in the diagnosis are: The history of injury, persistent nausea, hæmorrhage, prolonged shock, rise

of temperature, increasing rapidity and weakness of the pulse, increased frequency of respiration, rigidity of the abdominal muscles, persistent pain, with or without pressure, and the facial expression. Hæmorrhage can be avoided after operation by greater care in tying the bloodvessels in the mesentery, singly and not en masse; failure of the suture by better technique and the employment of Maunsell's method for end-to-end union; septic peritonitis by the liberal use of hydrogen dioxide where infection is known to exist, and leaving the abdominal cavity full of sterilized salt solution.

Finally, it may not be out of place to utter a word of caution as to the administration of the anæsthetic. It is generally intrusted to the least experienced, and therefore the least competent, assistant, and little attention is paid to the quantity employed. Operations of the character we have been considering must often of necessity be prolonged. It has been my custom when possible, since my experience in the first case, to have the anæsthesis in the hands of a thoroughly experienced and competent assistant. This lessens the mental wear and tear of the operator, and allows of more rapid work. By the use of Dawbarn's modification of the Clover inhaler, patients have been anæsthetized and kept unconscious for an hour with but four ounces of ether. They regain consciousness rapidly, have little or no nausea, and the danger of nephritis, which is getting to be a very frequent cause of death after operation, is materially lessened. With closer attention to details, quicker recognition by the general practitioner of the wisdom, at least, of early surgical advice, and, when doubt arises, giving the patient the benefit of it by an exploratory colliotomy, success will, in these cases, cease to be the

55 WEST THIRTY-SIXTH STREET.

## THE EFFECTS ON THE VOCAL CORDS OF IMPROPER METHOD IN SINGING.\*

BY H. HOLBROOK CURTIS, M. D.

It would be strange indeed if a larvngologist who was daily in the habit of examining very many throats of singers did not have his attention particularly attracted to the difference in the appearance of the glottis as the direct result of different methods of voice production. Several years ago-as early as 1884-I observed that many pupils of a certain professor of singing presented marked peculiarities in regard to the position of the free borders of the vocal bands. The slightly elliptical shape of the chink of the glottis which this class of pupils presented in emitting the usual sounds to allow the proper view of the larvnx led me to inquire as to the particular method of teaching which would produce in so many throats a typical appearance. I soon found out that these pupils were in the habit of taking daily exercises almost entirely on a single vowel, and that single vowel being the letter "O." The vocal

<sup>\*</sup> British Medical Journal, 1892, Max Withard's experiments.

<sup>\*</sup> Read before the First Pan-American Medical Congress, September,

cords appeared striated, with frequently a congested area at their anterior attachment. Frequently a nodule, more or less defined, would be observed about the center of the free edges on either cord; this is a picture which every laryngologist will recognize. Another type, of which the study is most interesting, is that of a class of pupils undergoing instruction at a conservatory where that pernicious French method, the so-called stroke of the glottis (coup de glotts), is daily practiced. In this type the writer has observed the middle third of the cords to be slightly bulged, the cords presenting a convexity in contradistinction to the concavity exhibited in the last group. These pupils had been singing chiefly on the vowel "A," pronounced as "ah" in English, and with the emission of each note the middle portion of the cords would clash and, by constant attrition, become hardened and callous. The cords in this particular type do not usually show congestion; their appearance is usually of a good pearl color and healthy looking in every way. The complaint which they make upon consultation is a difficulty in singing the so called mezzo voce and a lack of richness of tone and timbre, with extreme weakness of two or three notes in the upper-medium register. It was these two opposite appearances of vocal cords, which are every day observed in singers' throats, that led to an investigation of methods employed by the various schools of singing, and has opened up a field which I think has been entirely neglected, though of the greatest importance to every laryngologist who has to do with the singing voice.

Two names are intimately linked with the traditions of method in singing—those of the elder Lamperti (that illustrious exponent of the best Italian school), and Mandl, who, by his ingenious arguments, though founded on a false physiological basis, succeeded in completely overturning the art of voice production which previously had been taught throughout Europe. He substituted in place of the so-called Italian school a method of abdominal respiration, which was at once adopted in the Paris conservatory and has obtained to within the last three years an almost universal recognition in the best schools of the Continent.

It is the writer's purpose, without going too deeply into the history of singing, to discuss the various methods of respiration and initial tone production, and to show, by a series of experiments made upon individuals, the effects of certain methods of voice building, hoping to arrive at some definite conclusion as regards the proper exercise and position of the larynx, and consequently proper tension of the vocal cords during tone emission. For the brief historical sketch which I shall give I am indebted almost entirely to the able article of Dr. Joal, of Mont-Dore, which appeared in the Revue de laryngologie, d'otologie et de rhinologie, Nos. 8, 9, and 10, Paris, 1892. The position which Dr. Joal occupies at Mont Dore (the favorite resort of almost all the European artists) has enabled him to consult freely, for a number of years, the most distinguished vocal talent in Europe, and his views upon voice production should be carefully read by every instructor who wishes to profit by the exceptional opportunities which that author has enjoyed. One can not read his able discourse upon

the singing voice without feeling that his every utterance is ex cathedra. In 1842 Beau and Maissait divided the respiration of singers into three characteristic types-the superior costal, inferior costal, and abdominal. The superior costal may be illustrated as the breathing of a woman tightly laced, the respiratory expansion taking place chiefly in the cone of the thoracic cavity, the upper ribs, collar bone, and sternum rising and falling during the respiratory act. In the inferior costal type the inferior ribs (commencing with the seventh downward) are rotated and elevated, the sternum moving only in its inferior portion, the abdominal wall being contracted during the inspiratory act. In the true abdominal type the thorax is supposed to remain completely fixed, the diaphragm taking the ribs as a fixed point, lowering the abdominal viscera, thus distending the wall of the abdomen in inspiration. It is this latter type of breathing which has been taught for the last thirty years in France.

Mengozzi, together with the masters of one of the conservatories, determined upon the following rules illustrative of the breathing of singers: "The respiratory act in singing differs somewhat from that used in speaking. In speaking, the abdomen is distended in inspiration and recedes in expiration, while in singing the abdomen must be drawn in during inspiration, returning slowly to its natural state as the chest contracts in expiration, thus retaining as a negative force the air which has been introduced into the lungs."

In a revision of this method, published in 1866 by Baptiste, these laws are repeated, with the addition of a note by Dr. Mandl (the apostle of abdominal respiration), who advocates the advancing of the abdomen in inspiration. Mandl carried his point and his ideas became generally adopted by the conservatory. M. Bonheur and Dr. Cheval, of Brussels, advocated the superior costal type of breathing, in contradistinction to the method of Mandl. Mandl, in his work, states that the larynx becomes very much depressed and the glottis enlarged in the costal method of respiration. Joal answers him in these words: "We do not find this depression of the larynx referred to in any of our classical treatises on physiology, anatomy, or in any of the numerous works which have appeared since 1855 on laryngology; consequently, we suppose that writers do not share the ideas of Mandl on the subject. Besides, we have examined a number of persons whom we engaged to breathe alternately from the abdomen and from the shoulders. We ourselves, in singing, have often observed the movements of our larynx, and we have never observed that the clavicular inspiration caused the thyreoid to fall." Nicaise explains this fact by demonstrating, experimentally, that during strong inspiration the trachea contracts and becomes shorter, which draws down the larynx.\*

It is very difficult for a professional man to take cases of distinguished singers in his own private practice and hold them up by name as models of perfection of certain types. Joal made the assertion, in an article published in 1890, that great artists, especially women, used the supe-

<sup>\*</sup> Rerue de médecine, 1889.

rior costal method. The distinguished critic of *Le Temps* challenged Dr. Joal at once to mention some of these artists. The doctor responded: "I would be happy to gratify Mr. Weber's desire, but it is very difficult for a physician to go into personalities and to say that a certain singer is using a vocal method considered disastrous and execrable by masters of criticism." Melchissedec, however, offered himself as an example of the superior costal respiration, saying that it had enabled him to sing constantly for twenty-five years. Both his strength of tone and tremendous endurance, with an almost perfect glottis, attest that the method has not been injurious to him.

The abdominal method of breathing has many powerful advocates; M. Obin and M. Faure, for example, speak most highly of it; Shakespeare, of London, Behnke, and Lennox-Browne are also its advocates. The instructors of both methods are very apt to quote great artists as the exponents of their particular school. Joal cites the case of Rubini, the celebrated tenor, whom Massini and his pupils declare originated abdominal respiration. Bonheur, on the contrary, states that he expanded his upper chest, Walshe even going so far as to say that he fractured his collar bone in making a violent effort to reach "B flat" in The Talisman of Pacini. Lablache and Laget acknowledged that, in spite of long and attentive observation, they had not been able to distinguish in the theater how this illustrious tenor breathed. Joal goes on to state that the famous Lamperti is alternately represented as a partisan or opponent of the abdominal type of breathing, but I think that, having treated many of the elder Lamperti's pupils and interrogated them very particularly upon this question, I may unhesitatingly affirm that the elder Lamperti was a strong advocate of the lower costal respiration, always arguing that the abdominal wall should remain quiet, or be slightly drawn in during inspiration. The evidence of Campanini. Jean de Reszke, and Clara Heyen is in support of the foregoing. Joal says if we except the works of Laget and Bonheur, we find nowhere the praise of clavicular breathing in men. The ancient method of the Paris conservatory and the works of Maunstein, Caruth, and Manuel Garcia, all advise thoracic respiration by the elevation of the ribs and drawing in of the abdomen.

If we take up any work on the voice and study the photographic appearances of the cords during the emission of certain notes, we remark that the cords are not vibrating longitudinally, but that their free borders approximate, touch, or overlap, and that the posterior opening of the chink is longer or shorter, and different in appearance for each note. I wish to put on record here my opinion of the absolute impossibility of photographing the vocal cords during the proper emission of tone, from the very fact that the laryngoscopic mirror placed in the pharynx interferes with the right focus of the respiratory attack, and it is only possible to observe the vocal cords in the photograph when the so-called stroke of the glottis is used in the emission of a note. The photographs of singers' cords, and the de ductions which have been drawn from their appearance during the emission of different notes, only demonstrate, in every case that I have ever seen, that the larynx is elevated

by the pulling up of the thyreoid, the cords relaxed, and the free borders more or less approximated.

If we ask a singer who is in the habit of using the socalled high chest method of costal respiration to take a note (the attack entirely taken from the cords and focused in the masque, bringing into play the harmonics lent by the sound waves passing behind the uvula and soft palate), introducing the smallest possible size of mirror—so that the color given to the note by Nature's resonance pipes, the antra and nasal cavities, will be as little as possible interfered with—we are surprised to find that on the emission of every note of the soprano medium register the cords appear equidistant from each other throughout the entire extent that it is possible to see them.

The part which the intrinsic muscles of the larynx play in the tension of the vocal cords becomes an interesting study. It is very easy for us to see by the depression of the thyreoid how the cords must be elongated, but it is extremely difficult for us to comprehend the minute differences of tension caused by the movements of the thyreoarytænoid and crico-arytænoid muscles. I have frequently been surprised, upon examination of the vocal cords with the head held down, the chin resting upon the chest, to find the cords present a beautiful pearly appearance, entirely homogeneous; but upon attempting to show the patient his own cords by an adjustment of double mirrors, the head being slightly thrown back, upon the same note the cords suddenly have become dusky, semi-congested, and striated. How much of this is due to the slight elevation of the thyreoid cartilage, and how much to the intrinsic muscles of the larynx, or to the relationship between the chink of the glottis and the trachea, it is difficult to determine. To a careful study of these differences of tension am I indebted for the discovery of a fact which I here write about for the first time, the appreciation of which fact, however, has entirely changed my treatment of the singing larynx, and has caused me to institute a system of tone exercises by which certain intrinsic muscles of the larynx are so strengthened that any medical application through the medium of sprays, probangs, and I may say instrumentation, has ofttimes been entirely done away with.

If we take a good-sized laryngoscopic mirror-No. 4, for example-and ask a patient to sing "E" or "Ah," the cords come into view for two reasons: First, the epiglottis becomes more perpendicular, allowing a better view of the bands; and, secondly, the cords themselves are on a more elevated plane, owing to a slight elevation of the thyreoid cartilage and consequent relaxation of the intrinsic tensors of the cords. In this position we remark that the free borders of the cords come together in the anterior and central portions, and we are able to study the initial tone attack, the membrane separating as the tone bursts through the closed chink. This picture may be said to be an imitation, on a small scale, of the so-called stroke of the glottis. In this method of producing a tone, the initial attack being upon the cords themselves, the central portions of the cords necessarily touch. The peculiar muscular equilibrium which is employed in this mode of attack invites a reflex elevation of the soft palate, cutting off the oral from the

nasal cavities. As we look at this picture our minds revert to the singing teacher who commands her pupils to keep their palates up, sing in the back of their heads, and strike the glottis. Could ever villainy be more compounded ?. Let us take the same patient and require him to sing the same note, but in an entirely different way. We will first ask him to expand his upper chest, not necessarily by respiration, but by elevation of the superior ribs by a muscular effort, at the same time slightly drawing in the abdominal wall. We now introduce the smallest mirror and ask our patient to sing "A," pronounced as in law or maw. With this position of the larynx and muscular poise we observe two things: First, the epiglottis does not assume its most vertical aspect, not inclining as near the perpendicular, and the soft palate and uvula do not spring upward and backward to make the partition between the mouth and nasopharynx. Different in every respect is the tone produced by the cords, which may be assumed to vibrate longitudinally, but never touching each other in the middle portion, even in making the initial attack. The cords appear narrower, tenser, lower anteriorly, equidistant from each other, more homogeneous, and whiter in color.

These two pictures should be well considered, as they become the basis of criticism in distinguishing the correct and eliminating incorrect methods on the one hand in singers' voices, and of the greatest assistance to the laryngologist in correcting pathological conditions, the result of bad training. The proper appreciation of these opposite conditions and their effect on the quality of tone immediately calls our attention to the subject of respiration. Within the past three years the entire theory of musical education has changed in France, the explanation of this change being that there is at present a better appreciation of the influences bearing upon the production of tone and a better understanding of the physiology of the larynx, by reason of the advances made in laryngoscopy.

Modern teaching tends to cultivate tone harmonies and sympathy in the voice at the expense of brilliancy of execution. The same judgment should be exercised in the training of an individual who proposes to make singing his or her art as should be employed in advising the painter that his special forte lies in landscapes rich in color, in which he may give expression to his imaginative genius, rather than to the sterner facsimile of portraiture.

How many singers we hear whose technique and brilliant staccato in the Bell Song of Lakme calls forth our admiration and amazement, but who are absolutely unable to put any sympathy whatsoever into the simplest ballad! We should study color harmonies in music in the same way that they must be studied in painting. There is no rule for the palpitating sunlight effects and prismatic play of colors in the school of Claude Monet; it is certainly a subtle feeling which is given by an ingenious mingling of pure spectrum colors. In the human voice that added coloring of tone which appeals to the heart as well as to the ear of the listener must be brought about by the employment of those harmonics which are added to the original tone by intervibrations within the accessory cavities of the masal passages. To sing dans le masque, as the French say,

is to give this added richness to the initial tone; but to sing in this manner requires the soft palate and uvula to be lowered in the production of tone. Likewise, to make the purest initial tone from the cords, we must get the utmost possible tension, which may only be arrived at when the thyreoid is depressed, for, in proportion as the thyreoid is elevated, the cords tend to assume the base of a right-angle triangle instead of its hypotenuse. Several elements besides this enter into the question of greatest possible tension, one of the most important of which is that the trachea be drawn down to assume the position that it takes when the apices of the lungs are filled to their greatest extent with air. One of the greatest singers the world has ever known told me that the reason that he adopted a fixed high chest was that he had found, after the removal of a papilloma from one of his cords, that the only way in which he could be at all sure of his voice while singing was by the maintenance of the so-called high chest respiration. This is easily explained by the fact that in this position, the upper ribs remaining fixed, the apices of the lungs always remain in contact with the thoracic wall, expanded to their fullest extent, the cords being kept in their state of greatest possible tension. In this position the breathing becomes entirely inferior costal and diaphragmatic. The position of the thorax, as indicated above, permits the lungs to expand to their fullest extent, thus adding a secondary resonance to the voice from below-a sort of complementary timbre, the fixed upper thorax allowing of the least possible change of color during tone production.

It is this combination of facial and thoracic tone fortification which gives thee normous carrying power to tones produced by this method. For a number of years before I made a special study and estimated the great significance of these factors in singing, I deluged the throats of singers with sedative and astringent sprays when their cords appeared congested and swollen, often presenting nodules in their center which I had never previously recognized as being due entirely to singing with an improperly poised larynx.

I may cite several cases to show you the difference, from a medical standpoint, in the treatment of the singer's throat, where I now substitute respiratory and tone exercise for the amelioration of conditions that I have always been taught were only to be cured by rest and the diligent use of drugs. The cases I cite are typical of a class of singers that I have treated with equally good results since I have made a particular study of the peculiar value of the proper tone production in the human voice.

Case I.—The first day of January last I was consulted by Miss F., aged twenty-three years, who had had a contrait voice of large power which she had employed constantly for several years, and had finally, after a prolonged concert tour with a well-known orchestra, entirely broken down. Her cords were dark red, with a slight nodule in the middle of either band; she complained of great pain in producing her notes, and her medium register had no power in it whatsoever. She had been told by two of the best authorities on the throat that she must not sing a note for a year, and must have her cords painted with astringent solutions and tone up her general health. Upon testing her voice, I remarked an extremely breathy tone and clavicular respiration.

In accordance with the principles which I have attempted to demonstrate, I forbade her speaking a single word for a week, but placed her at once upon the so-called inferior costal respiration, maintaining a high chest, and giving her directions to take a medium "C" with the chin almost resting upon the clavicle, singing the word "ma" for five minutes of each hour of the day, the tone first to be focused in the face with the mouth closed, and the attack to break upon the lips as much as possible on opening the mouth. At the end of seven days the cords, instead of presenting an elliptical appearance, were straight, and the nodule was so far rotated upward on either cord that it did not touch the nodule of the opposite side in the emission of tone. At the end of the week this young lady, who considered her voice hopelessly destroyed, having acquired a new method of respiration, sang in a concert. She has since sung regularly in church, in many oratorios during the winter, and is at present singing three times a week in grand opera, learning new rôles continually, apparently perfectly restored. She tells me her voice is far more powerful than she had ever dreamed of.

Case II.—Miss P. H. consulted me on March 2d in great distress. She was obliged to sing in a comic opera on that evening or close the theater. Examination showed inflamed and bulged cords with great hoarseness in the speaking voice; middle register impossible, but the high notes obtained with great effort. I sent her at once to my assistant, who gave her exercises to maintain tension, and at the end of an hour's work with tension exercises and inferior costal breathing the cords responded and she sang with ease.

Case III.—Miss H. B. consulted me in May, having lost her position as prima donna by reason of loss of voice. Had been constantly treated. Her cords showed the nodules of attrition, the result of the employment of the coup de glotte and faulty respiration. In this case a week's work caused the nodules to disappear. She adopted a proper laryngeal poise and again assumed the leading rôle.

Observation.—In this class of cases rest causes a relaxation of the cords and singing becomes impossible for some time, whereas constant work, with tension of the cords and non-approximation of the same, gives immediate relief.

Case IV.—Fraulein K. consulted me in the spring. Her cords appeared swollen and the membrane was injured but not hyperæmic. Had been obliged to cancel her engagements and return to New York for treatment. I recognized the familiar picture and sent her to my assistant, who cured her in a week without other treatment than the establishment of a proper laryngeal poise.

With many cases like these which I might cite, may I not be excused in my assumption in calling attention to what I consider the most important ground principle of the singer's art—namely, the proper employment of the muscles of respiration, the poise given the cords, and the proper use of the intrinsic muscles of the larynx, not forgetting the bringing into play of the accessory cavities of the face, which lend so much color to the tone, removing entirely from the cords the deleterious effects of an improper initial attack?

To rehearse briefly the deductions which I have attempted to draw from my argument, I maintain that the best method of respiration is the inferior costal or diaphragmatic, faithfully maintaining the elevation of the upper ribs without raising the shoulders. Next in importance is the depression of the thyreoid cartilage, brought

about through the agency of the crico-thyrcoid muscles, and the pulling down of the trachea, by increasing the capacity of the upper lobes of the lungs—anatomically speaking, a pose-causing the thyreo-arytænoids muscles to produce tension, instead of the crico-arytænoids. Be careful that the initial attack is removed entirely from the cords. Lower the uvula and soft palate, that the sound-waves may obtain their intercurrent vibrations or harmonics, by partly passing into the nasal cavities from behind. Let us not fall into the error that the roof of the mouth alone is the sounding board of the singing voice, for without that added richness and timbre to be given by calling into play Nature's resonance pipes, the nose and its accessory cavities, we may sing, but the singing is at the expense of the cords, and the life of the voice is necessarily shortened.

If I have said enough to arouse a new interest in what I consider a most necessary accessory to laryngology, I shall feel amply repaid for my endeavors to set the theme before you in a clear and comprehensive manner.

#### A GUIDE TO

# THE STUDY OF SURGICAL DIAGNOSIS DURING BEDSIDE INSTRUCTION.

FOR THE USE OF SENIOR STUDENTS.

BY FRED WALKER GWYER, M. D.,

ADJUNCT PROFESSOR OF SURGERY
AT THE UNIVERSITY OF THE CITY OF NEW YORK, MEDICAL DEPARTMENT
VISITING SURGEON TO BELLEVUE,
AND CONSULTING SURGEON TO BETH ISRAEL HOSPITALS, ETC.

During several years of clinical teaching the writer has been impressed with the difficulties met with by students in arriving at correct diagnoses of cases presented, and their proneness to jump at conclusions often after a most superficial examination and without the slightest knowledge of the causes leading to the disease or injury under consideration.

While, no doubt, those of large clinical experience can very often make a correct diagnosis from general appearances, it is obviously unwise to allow a student to do so.

I think that all clinical teachers will agree with me that there has been a want of system in treating the subject with the student; and that the student, having only his text books to refer to—and in these finding nothing to his purpose—looks to his teacher entirely for such instruction.

The time at the disposal of the teacher being limited, it becomes a question of how best to present the subject to the student in a concise form and still completely enough to impress upon him the necessity of and reasons for using care and thoroughness in taking histories; and also to give him a foundation upon which he can build a system which may be followed while in college and afterward with advantage to himself and his patients.

After a thorough trial of the following method, I am emboldened to present it to students and teachers as the one which I have found best adapted to the needs of both. The method presupposes a knowledge of surgery such as the student entering upon his senior year has already acquired from text-books, recitations, and didactic lectures;

and it will be found applicable to all surgical cases in what ever order they may present themselves for clinical use.

### PRELIMINARY QUESTIONS.

Name of patient.
 Address.
 Nativity.
 Age.
 Sex.
 Color.
 Social state.
 Business.

All of the above questions are important and should be asked not only for record, but as having a possible bearing on the diagnosis. The answers to the last six questions in particular have a value which should not allow them to be overlooked.

- I. Family History.—1. Father, mother: If living, the age and state of health of each should be inquired into. If dead, the age at death and causes. In some cases, where knowledge of hereditary disease in the parents is denied, the histories of the grandparents, uncles, and aunts on both sides may lead to the required information.
- Brothers, sisters: The number living and the state of health of each. The number dead, respective ages at death, and causes of death.
- Children: Number living, ages, state of health of each. Number dead, ages at death, causes of death. Miscarriages—number, at what months.

II. Personal History.—Under this head inquiries should be made concerning—

- 1. Former diseases and their treatment.
- 2. Former injuries and their treatment.
- 3. General health.

Often a knowledge of a former disease or injury will be found useful. Sometimes a patient not able to give positive information regarding a disease or injury will, from his description of the treatment pursued, enable the examiner to make a correct surmise as to what it may have been.

- III. History of Present Disease or Injury.—1. If disease: a. When it began. b. Where it began. c. How it began. d. Subsequent course. e. Former treatment and operations.
- 2. If injury: a. When it occurred. b. How it occurred. c. Part injured. d. Physical and mental condition immediately after. e. Subsequent course and treatment.

The value of nearly all of these questions is apparent. Questions d will be found very necessary; questions e, besides their diagnostic value, will, in cases where many remedies have been used with or without benefit, be of help in outlining the treatment.

- IV. Physical Examination.—1. a. Pulse. b. Temperature. c. Respirations.
- 2. Inspection: a. Color. b. Size. c. Contour. d. Comparison with opposite side; when the member or organ injured or diseased has a duplicate, this should always be made. e. Remarks as to sinuses, ulcers, discharges, eruptions, etc.
- 3. Function: a. The presence or absence of active and passive motion. b. Use of the member or organ.
- 4. Palpation: Whatever may be perceived by means of the finger tips. The presence or absence of pain, crepitus, change of color on pressure, fluctuation, ædema, deep irregularities, undue consistence, mobility, etc.
  - 5. Percussion: a. Superficial. b. Deep.

- Manipulation: Whatever may be perceived by means of the hands. The presence or absence of motion, mobility, pain, crepitus, etc.
- 7. Localization: In employing palpation, percussion, and manipulation, the necessity for localization should be borne in mind. Tumors should be mapped out, particular spots of pain noted; points at which crepitus is most distinct, points of false motion, degrees of mobility in various parts, and the extent and direction of irregularities, pain and false motion noted, etc.
- Instrumentation: This includes the use of the hypodermic syringe, probes, sounds, electrodes, electric lights, stethoscope, tape-measure, and all other diagnostic instruments.
- Examination of excretions: a. Pus or other discharges.
   Urine. c. Fæces.
- 10. Microscopical examination: a. Pus or other discharges. b. Urine. c. Fæces. d. Growths, etc.
  - V. Diagnosis .-

1. The examiner will now have a mass of information gathered from the history and examination of the case which may be found to apply to one or more of several diseases or injuries. If he will select the two, three, or four diseases or injuries which are more particularly indicated, and group under the head of each the information especially applying to it, it will be found that, in the large majority of cases, the summary will lead him to a correct diagnosis.

Great care, however, must be taken not to give undue prominence to a minor symptom.

- In the more difficult cases it is proper to use the method of exclusion.
- 2. Exclusion: Every disease or injury has one or more symptoms which are characteristic, perhaps pathognomonic, and the absence of these symptoms in a particular case may rightly lead one to exclude that disease or injury, and so, working backward from a knowledge of what should be if the disease were such, we are able eventually to exclude all that it is not and make a diagnosis by exclusion.
- VI. Prognosis.—1. Immediate results. 2. Distant results. 3. Time.

In stating the prognosis it is necessary to give an opinion as to the immediate outcome of the case, whether it is to be rapidly fatal or not, whether it means partial or complete disability, and the probable length of time to a fatal ending or comparative cure.

The ultimate results will be asked for, and one should be prepared to state what they will be regarding life, usefulness, comfort, and time.

- VII. Treatment.-1. Primary: a. General. b. Local.
- 2. Intermediary: a. General. b. Local.
- 3. Secondary: a. General. b. Local.

The primary treatment refers more particularly to injuries, and consists essentially of the aid which is given immediately after its reception. Generally, shock is to be treated; locally, hamorrhage controlled, temporary splints or other dressings applied, etc.

The intermediary treatment refers to disease or injury, and is that which is given with a view to fitting the patient for the secondary treatment. Generally, in disease, a course of tonics, proper food and hygiene, preliminary to an operation; in injury, the treatment of shock and general conditions. Locally, in disease or injury, temporizing dressings.

The secondary treatment refers to permanent or final treatment. In disease, perhaps an operation; in injury, permanent dressings. The use of the terms general and local will be readily understood.

VIII. Classification of Cases.—One having carefully considered the foregoing plan will see that all cases may be assigned to one of four classes:

- 1. Cases of injury. Of this class a fracture is a good type. It is rarely necessary in considering a fracture to inquire into the family history or into what diseases the patient may have had. Infrequently, however, one may find such knowledge of greatest importance, as is witnessed by cases of delayed union after fracture in syphilities.
- 2. Cases of acquired disease. The tertiary lesions of syphilis (bone necroses, gummata) form a good type for study. In these the personal history of disease is of great importance, the family history being useful only secondarily or for purposes of exclusion.
- 3. Cases of hereditary disease. Tubercular disease in its various forms is perhaps the most common and usually furnishes a good type. The family history in this class must be very complete and is of fully as much importance as the personal history of disease.
  - 4. Mixed cases. Under this head may be placed—
- a. Cases of injury complicated by acquired or hereditary disease.
- b. Cases of disease complicated by injury or some other acquired or hereditary disease than the one originally under observation.

In conclusion, it is well to state that the examiner must be thorough and persistent in his interrogations. This cau tion applies especially to the management of hospital and dispensary patients. Aside from the wish to deceive or withhold information which a few patients may exhibit, the average intelligence of such patients being low, the questions must be explicit and perhaps oft repeated and their form changed to elicit the desired knowledge.

332 LEXINGTON AVENUE.

## THE EYE TREATMENT OF EPILEPTICS.

A CRITICAL REVIEW OF

CERTAIN FACTORS THAT MAY LEAD TO CONVULSIVE SEIZURES, AND THE TRRATMENT OF EPILEPSY WITHOUT DRUGS.

BY AMBROSE L. RANNEY, A. M., M. D.

(Continued from page 51.)

Case XIV. This case is not as yet of much value in determining the results of eye treatment upon epilepsy; but it resembles. Case XIII very closely and illustrates that a perfectly

normal refraction (connetropia) may coexist with a marked heterophoria almost totally latent. The terrible accident that befell this patient has delayed until recently further investigation of the heterophoria.

Case XV was an extremely interesting one to me for the following reasons: The epilepsy had been of the nocturnal type; it had not been benefited by bromides; the patient had inherited (as shown by my case records) marked tendencies, on both the maternal and paternal side, to eye defects; one sister had been a source of great anxiety to the parents for many years from extreme nervous debility that seemed incurable, and she had been restored to perfect health while under my care through eye treatment without drugs; finally, one brother had manifested epileptic tendencies.

A perfect recovery from a life-long dependence upon cathartics is also another evidence of the improved nervous tone of this patient.

Case XVI is yet under observation. It is one of the most difficult cases to solve that I have ever encountered. Thus far the results of eye treatment seem to have been highly satisfactory.

Case XVII illustrates some excellent results in correcting heterophoria, with apparently negative results upon the epileptic seizures. The seizures are so infrequent that it is difficult to tell just what the ultimate effects of the eye treatment may be. I am inclined to suspect that some form of uterine or ovarian reflex irritation exists at present in this case.

Case XVIII shows that excellent results from the oculistic standpoint have been obtained, with equally marked benefits to the patient in respect to her epileptic seizures.

Case XIX illustrates extreme and unequal refractive errors in addition to extreme heterophoria. The results have thus far been quite encouraging.

Case XX shows that better results have followed eye treatment than have ever been obtained by drugs. There is reason to hope for permanent relief from epileptic seizures.

Case XXI is not as much improved as some of the preceding cases, but he is as well without drugs as he ever was when under their influence.

Part of the operative work in this case was done before I saw the patient.

Cases XXII and XXIII are incorporated in this brochure (in spite of the fact that the results of eye treatment are still in abeyance on account of the short interval that has elapsed since the heterophoria has been partially rectified) because they illustrate one important point—viz., that very extreme latent heterophoria can exist as a cause of convulsive scizures independently of any marked error of retruction.

In Case XXII it was deemed wise to give +1.00 s. glass for constant wear; but in Case XXIII almost absolute emmetropia was found.

I do not personally consider that any ground for argument exists to-day regarding the claim heretofore made by some oculists of repute—viz., "that all heterophoria is due solely to errors of refraction." If such a statement is to-day believed by any one who has carefully investigated heterophoria, I think that Cases XXV, XXIV, XXIII, XVII, XV, XIV, XIII, VI, and I ought to disprove it.

Case XXIV was attended with outbreaks of apparent epileptic insanity, in addition to periodical attacks of continuous epileptic seizures of so violent a form as to justify the use of chloroform. Very frequent attacks of petit mal would also occur in spite of large doses of bromide salts.

The refractive errors were insignificant in this case, but the latent heterophoria was extreme. The case is incorporated chiefly to illustrate this point, as the eye treatment was aban-

doned before any beneficial results could reasonably be expected.

Case XXV again illustrates extreme latent heterophoria, independent of any marked error of refraction. The results in this case can not as yet be regarded as final. Some latent heterophoria still manifests itself at times.

In concluding this article (prior to reporting the detailed histories of twenty-five cases of epilepsy) I present a table that may possibly shed some light upon the eye conditions \* that are apt to be encountered in patients afflicted with this malady:

Summary of the Eye Defects detected in the Cases reported.

	No. of cases.	Per cent.	Remarks,					
Esophoria	23	92	Corrected in every case by graduated tenotomies upon the internr or advancements of the externi.					
Exophoria	2	8	Corrected in every case by graduated tenotomies upon the externi.					
Hyperphoria	7	28	Corrected in every case by graduated tenotomies.					
Heterophoria	25	100	Is rarely absent in epileptic subjects.					
Orthophoria			I regard this as an extremely rare condition in epileptics.					
Hypermetropia	19	76	Corrected in most cases by glasses for constant wear,					
Myopia	2	8	Corrected by glasses if in excess of two dioptres.					
Myopic astigmatism	3	12	Fully corrected by glasses in every case.					
Hyperopic astigmatism.	6	24	Fully corrected by glasses in every case.					
Emmetropia	4	16	A somewhat rare condition, even in health.					

At a late meeting of the Ophthalmological Society of the United Kingdom a report of the refractive conditions of epileptics was made by Mr. Dodd (based upon the examinations of a hundred epileptic subjects as contrasted with similar tests upon fifty healthy persons). The effects of treatment by a correction of the refraction alone by glasses were also reported.

Out of a hundred epileptic subjects, seventy-five were found to require glasses and were directed to wear them. Only fifty two of these patients were faithful in obeying the instructions. Of these fifty-two, thirteen had no attacks for an interval of from one to two months, thirty-six were more or less benefited, and three were not apparently influenced by the correction of the refraction.

The conclusions drawn by Mr. Dodd were: (1) That errors of refraction may excite epileptic seizures; (2) that the correction of refraction is of value in the treatment of epilepsy; and (3) that other sources of irritation may be suspected when a correction of refraction fails to afford marked relief. \( \frac{1}{2} \)

To any one familiar with the later methods of investigation and treatment of heterophoria the investigations of

Mr. Dodd must seem singularly incomplete. Yet it is interesting to note that the correction of refraction alone accomplished enough in cases of chronic epilepsy to warrant a verdict in favor of the eye treatment.

I admit that any deductions regarding the eye tests in epileptic subjects derived from twenty-five cases can not be regarded as final; still I find that the preceding table indicates what to my mind would be about the average results of my personal examinations and treatment of quite a large number of epileptics during the past ten years (a period when I first began to record, in every case, the results of examinations of the eyes).

#### CONCLUSIONS.

I would formulate my conclusions, as the total result of my observations of the eyes of epileptics, as follows:

- In epilepsy I regard an examination of the eyes (for errors of refraction) and of the eye muscles (for heterophoria) as the first and perhaps the most important step toward a search for sources of reflex nervous disturbance.
- 2. No final conclusion should be reached regarding the presence or absence of heterophoria until sufficient time, patience, and skill has been bestowed upon the investigation by one who is thoroughly familiar with and practices the later methods for the determination of "latent" heterophoria.
- 3. All preparations of bromides and other drugs that tend to control the seizures should be withheld, as a rule, from an epileptic patient until all possible sources of reflex irritation have been scientifically sought for and, as far as possible, relieved.

There may be justifiable reasons, to my mind, for exceptional departures from this rule; but I wish to emphatically raise my voice here in protest against the prevalent system of drugging epileptic patients from the date of the appearance of the first fit without any attempts being made to ascertain what the causes of the epilepsy may be.

4. I strongly advocate the employment of atropine in every case before a final decision is reached regarding the refraction of an eye.

I also believe that in epileptic cases it is wise to insure a full correction of any existing astigmatism (by glasses to be worn constantly in well-fitted spectacle frames), and as near a full correction by spherical glasses of any latent hypermetropia that is detected as the patient can be made to tolerate, even if atropine has to be instilled at intervals into the eyes of the patient for several weeks to prevent a return of ciliary spasm.

I have observed many cases of chronic epilepsy that have been relieved of all convulsive seizures so long as the full effect of atropine upon the ciliary muscle was maintained.

- 5. No promises that absolute cure can be effected by eye treatment should ever be made to an epileptic; but it is usually safe for the physician and patient to hope that a radical correction of marked heterophoria and abnormal refraction will eventually be followed by decided and permanent benefits.
  - 6. The results in all cases thus far treated by me seem

<sup>\*</sup> The meaning of the terms used in this table and the histories that follow have been given in this article on a preceding page.

<sup>†</sup> In this collection of cases the percentage of emmetropia appears to be greatly in excess of what is usually encountered.

<sup>‡</sup> Italies my own.

to warrant the conclusion that at least ninety per cent. of chronic epileptics have been better without bromides, after a satisfactory correction of their eye defects, than they ever were when subjected to the influence of drugs. Some have apparently been cured. (See Cases I, II, IV, V, VI, VII, X, XIII, and XV.)

It should be remembered that a victim to chronic epilepsy who is rendered by any treatment as free from attacks without the bromides as when under their deleterious influence has been very markedly benefited; again, that if a marked diminution of the attacks has been effected, the patient has double cause for gratitude; finally, that if the attacks are arrested in toto without drugs, it is to-day one of the most remarkable facts recorded in medical literature.

7. In cases where negative results have been observed in spite of a satisfactory investigation and correction of marked heterophoria and abnormities of refraction, I would deem it wise before resorting to drugs for epileptic seizures to search for other sources of reflex peripheral irritation (such, for example, as bad teeth, phimosis, rectal or uterine disease, scars, etc.).

Furthermore, the detection of chronic kidney disease, syphilis, organic brain lesions, and depression of the skull, is most important prior to the beginning of eye treatment or a search for other forms of peripheral reflex disturbances.

- 8. The treatment of heterophoria by prismatic glasses alone is not curative; nor, in my opinion, are very marked beneficial results to be expected from them. Prismatic glasses are valuable aids, however, in determining the existence and amount of "latent" heterophoria prior to the radical correction of such defects by graduated tenotomies.
- 9. The duration of the eye treatment of epilepsy varies with the eye problems encountered.

The establishment of orthophoria is not commonly effected in epileptics inside of one year; and long intervals of rest between the surgical steps may be demanded and thus extend this limit of time to two or even three years.

For the past five years I have refused to begin work upon the eyes of any epileptic unless I was assured that I could control the patient for a period of at least twelve months, and see the patient at such intervals as I deemed necessary during that period. It is better in this work "to be sure than sorry," and experience has taught me that it is much safer to do it slowly than rapidly.

With a full knowledge of the method, its intricacies, and its difficulties, conclusions should never be too hastily arrived at in any given case. Those who have had the largest experience may occasionally make mistakes in judgment when a peculiarly complex problem is presented for solution. How much easier is it, therefore, for one with a limited experience to fall into error! The story is told that a selection for a pilot of a vessel laden with precious merchandise which was to enter a harbor full of sunken ledges and sandbars was once being made. One by one the applicants told a tale of uninterrupted successes. Finally one pilot was accepted simply because he said, "I

ought to know the channel, as I've wrecked a ship on every rock in this harbor."

So it is with many cases of epilepsy, chorea, insanity, and kindred nervous affections. These patients have, as a rule, acquired and constantly practiced from birth certain faulty combinations of the various eye muscles in order to enable them to use the eyes together.

They are often able, by the aid of such unnatural combinations, to simulate a condition of apparent equilibrium of adjustment of the eyes, although a very serious expenditure of nerve force may be demanded of them in order to do so. They are naturally unconscious of the eyestrain, because they think everybody does as they do in order to see. They often have no eye symptoms. They practice these "tricks of adjustment" instinctively, not as an act of volition; and they have generally to be taught, by the aid of prismatic glasses and other recognized steps, to abandon them and thus to disclose the actual maladjustment of their eye-muscles which has entailed upon them this long-continued leak of nerve force.

10. Too much stress can not be laid upon the importance of accurately centering all spherical and cylindrical glasses to the pupils when prescribed.

An imperfectly fitted frame may prove a source of great injury to a patient.

Moreover, a decentered glass may often lead a careful observer into serious error respecting heterophoria.

It is remarkable how few opticians are properly educated in the fitting of frames. A casual glance at the eyeglasses and spectacles worn at social gatherings and in street cars, theatres, etc., by people able to purchase of the best opticians, will demonstrate the statement that but a very small percentage wear glasses that are even an approach to the proper relationship to the pupils.

It has been a rule in my office for years to allow no patient to wear a glass that I have not personally tested and passed upon as properly ground and centered to the pupils. I also instruct each patient regarding the necessity of having the frames straightened when bent or whenever the lenses tend to droop.

I do not believe in decentering any glass, even intentionally to take the place of a prism.

Some months ago a patient took the long trip from Tacoma to New York in order to consult me regarding a sudden change in the vision of one eye that greatly alarmed him. I had previously given him for constant wear cylindrical glasses in a spectacle frame and he had changed them to a pair of eye-glasses. The bending of the frame had changed the axis of the cylinder of the right eye. Within a space of five minutes this was corrected, and all his alarm disappeared at once because his vision immediately became normal.

11. The objections that are raised before patients by many physicians and some oculists to the performance of a graduated tenotomy upon an eye muscle "because of its risk, danger of overcorrection, etc.," too frequently cause unnecessary alarm and often prevent patients from obtaining the relief that is within their grasp, and which prismatic glasses have not and will not afford.

Since the employment of cocaine as a local anæsthetic the patient suffers no pain during this operation and but little discomfort after it.

Furthermore, the operation as now performed does not necessitate any confinement to the house, and all surgical dressings to the eye are avoided.

That the successful operator must possess skill and a high grade of technique (acquired by constant practice in that special line of surgery) is apparent; but I believe that the danger of overcorrection is very small in operating properly for heterophoria, and, in the hands of an expert, an overcorrection is very readily controlled and rectified. I do not recall a case within the past eight years where I have had a moment's anxiety resulting from an overcorrection, although I have in that time performed at least one thousand graduated tenotomies upon the muscles of the orbit.

Case I.—Mr. B., aged twenty-six years, machinist, married-Patient was referred to me by Dr. E. W. Hedges, of Plainfield, N. J., on July 30, 1892.

Family History. — No hereditary tendencies to nervous troubles. Mother has headaches. One uncle had phthisis.

History of the Case.—Was perfectly well up to the age of twenty-four. Had an attack of petit mal with "spitting of blood." Had five attacks during the next twelve months. They then began to be frequent, and within the next year six or seven attacks daily were liable to occur. Bromides were begun two months ago and have given little or no relief. From two to ten attacks daily now occur. The patient "does not fall in these attacks, but twitches some and becomes stiff." He is only momentarily unconscious and often can talk. His eyes feel very queer during the attack, the pupils dilate, and the conjunctiva is often inflamed after the attack.

Patient does not smoke, nor drink anything but beer with his meals. Has never had any venereal disease. He sleeps well and has a good appetite. Has no marked tendency toward constipation of the bowels. No history of an exciting cause for the seizures can be elicited. Urine normal.

Eye Defects.—At the first examination, an apparent slight hyperopic astigmatism; but under atropine a latent hypermetropia of only one half dioptre.

Apparent esophoria of 1° at first visit, but within a few weeks 8° of esophoria disclosed itself, with a marked outward jump when the exclusion test was employed. With the Maddox-cylinder test, esophoria of 10°; adduction, 38°; abduction, 2°; sursumduction—right, 2°; left, 2°; no hyperphoria.

This patient, on cessation of bromides, had thirty-nine attacks during first week, and sixty-seven attacks during second week. During part of this time he was wearing prismatic glasses, for the purpose of developing the "latent" esophoria that disclosed itself with great rapidity.

Treatment and Results.—Three graduated tenotomies have been performed upon this patient for the relief of his esophoria, as it disclosed itself from time to time. From the first operation the attacks became less frequent and the patient greatly improved in his general buoyancy of spirits.

The last record of any eye tests of this patient was made on April 15, 1893. He had been entirely free from any attacks for thirteen weeks. His adduction was 33°; abduction, 7°; sursumduction—right, 2°+; left, 2°+; no hyperphoria; esophoria, 0.75°.

A letter from him dated October 6, 1893, makes no mention of any attack up to that date—a period of over ten months without seizures, and with a total cessution from all drugs.

A subsequent letter, dated November 19, 1893, says: "With the greatest of pleasure, I can say that I have not since you saw me last had any attacks, or even the slightest symptom of any."

Case II.—Mr. F., single, accountant, aged twenty-seven years. Patient was referred to me by Dr. J. B. Bissell, of New York, on September 2, 1892.

Family History.—All mother's family died of phthisis except one. All maternal relatives have headaches and are very nervous.

History of the Case.—Patient has always been exemplary in his habits; neither smokes nor drinks, and goes to bed at regular hours.

Until the age of twelve years the patient was apparently well and strong. During that year he fell from the woodshed on to the ice and had a hæmorrhage of nearly a quart from the lungs. An epileptic convulsion followed. At intervals, for a long time, during the night he would have peculiar attacks associated with a peculiarly hard breathing and slight tremor. He has always been a victim to headache. These at times were terribly severe.

From the date of his first convulsion (fifteen years ago) this patient was placed upon the bromide treatment, which he has kept up ever since with varying doses. He has taken chiefly a combination of bromide of sodium and ammonium.

He has been a chronic dyspeptic for years. No evidence of depression or injury to the skull exists.

In spite of bromides, severe epileptic seizures would occasionally occur. During the first seven months of 1892 patient had four epileptic seizures at intervals of about two months apart.

He consulted Professor E. G. Janeway, of New York, in the summer of 1892, who advised him to see an oculist and continue his bromides. Week myopic cylinders were prescribed by Dr. St. John, of Hartford, Conn., which he has worn constantly for the past few months. His dyspeptic troubles seemed to be much lessened by the use of glasses, but an epileptic attack followed in about five weeks in spite of his bromides.

Eye Defects.—Under atropine this patient disclosed the following refractive condition: 0. D., V.  $\frac{9}{8}$ % with +0.50 c., axis 90°; O. S., V.  $\frac{2}{2}$ % with -0.50 s.  $\bigcirc -0.50$  c., axis 180°. He also showed left hyperphoria, 1°; esophoria, 2°; adduction, 11°; abduction, 5°—; sursumduction—right, 2°+; left, 3°.

On the following day the effect of esophoria prisms was tried upon this patient. He showed within three hours unconquerable homonymous diplopia (with a red glass) and 6° of esophoria. Abduction, 0°.

Treatment and Results.—Graduated tenotomies were performed upon both interni within a space of two weeks, after which he showed left hyperphoria, 0.5°; esophoria, 0.75°; adduction, 21°; abduction, 7°; sursumduction—right, 2°; left, 8°.

Six weeks afterward he reported that his digestion was very much improved; that he had had no attacks for six weeks, and taken no bromide for four weeks. He was wearing constantly a full correction for his refraction.

Later on an investigation of his hyperphoria disclosed 4° of left hyperphoria and a 3° prism was incorporated in his glass. At this time he showed esophoria, 0.5°; adduction, 18°; abduction, 5°+; sursumduction—right, 0°; left, 6°.

When four months had passed without an attack, the patient again visited my office. He reported that all evidence of chronic dyspepsia had absolutely disappeared and that he no longer had any distress in his head.

If his glasses are removed he has unconquerable vertical diplopia. During all this period he had used his eyes for bookkeeping throughout the entire day. His eye tests showed: Left hyperphoria, 4.5°; esophoria, 0.5°; adduction, 17°; abduction, 5°+; sursumduction—right, 0°; left, 8°—.

The right inferior rectus was now operated upon for the correction of the hyperphoria. After this operation the patient showed: Left hyperphoria, 0.5°; esophoria, 0.5°.

Three days later there was adduction,  $23^{\circ}$ ; abduction,  $5^{\circ}$ +; sursumduction—right,  $3^{\circ}$ -; left,  $3^{\circ}$ -; left hyperphoria,  $0.25^{\circ}$ ; esophoria,  $0.5^{\circ}$ .

A letter, dated March 13, 1893, says: "Saturday will be seven months since the last attack, and I am feeling simply immense."

On April 17, 1893, the following muscular tests were recorded: Vision  $\frac{2}{30}$  in each eye with the glasses prescribed; no vertical or lateral muscular defect; adduction,  $32^{\circ}$ ; abduction,  $7^{\circ}+$ ; sursumduction—right,  $2^{\circ}$ ; left,  $2^{\circ}+$ .

Since the last note the patient reports that on July 23, 1893, he had a very slight seizure on going to bed, the first and only one he has had since coming under my care. He has had none since (up to January 1, 1894).

Case III.—Master G., aged ten years. Referred to me by Dr. A. D. Stewart, of Port Byron, N. Y., on May 5, 1893.

Family History.—The father came with the boy and was a picture of robust health. No epilepsy had appeared in his ancestry.

History of the Case.—This boy came to my office accompanied by his father and Dr. Stewart, who led him along by the hand as he would a child of much younger years. He had a peculiar vacant, semi-idiotic expression that strongly indicated his enfeebled mental condition. His head was one of those peculiar heads that was nearly spherical, with eyes set wide apart, a small nose, and mouth half open. He was singularly sluggish both in his mind and in his movements, and was justly regarded by the doctor and by his parent as partially idiotic. His father was a farmer, and the boy had been brought up on the farm.

The clinical history, as well as the family history, was crude and imperfect. The boy had had innumerable epileptic fits, which nothing had seemed to relieve. On his way from Elmira, N. Y., to New York city he had had several attacks on the train, and had sat throughout the trip without hardly moving from his seat, except when in convulsion. He evinced no interest in any of his surroundings, did not look out of the window at the landscape, and in all other ways manifested his defective mental condition.

Eye Defects.—A casual glance at the patient showed that he had an approach to double convergent strabismus. Vision,  $\frac{20}{5}$  in each eye before atropine was instilled. Under homatropine a latent hypermetropia of +1.75 dioptres.

On exclusion of either eye a marked jump outward confirmed the existence of esophoria of a high degree. All attempts to get accurate muscular tests proved futile, as the patient suppressed images in spite of all my efforts to make him show his ocular maladjustment. As nearly as I could make out, 10° of manifest esophoria, at least, existed.

A free graduated tenotomy was performed upon both interni on the same day, with the effect of causing a remarkable change in the looks of the boy's eyes. A full correction of the hypermetropia (+1'75 s.) was ordered for constant wear, in strong spectacle frames, and an atropine solution ordered for instillation into the eyes.

On the following day I succeeded in getting the following tests with fair accuracy, the suppression of images having been partially overcome: Esophoria, 5°; left hyperphoria, 1°; abduction, 6°+. No jump on exclusion of either eye.

The father and Dr. Stewart reported that, on the day of the operations (within two hours following them), the boy had

amused himself all the afternoon counting pennies and playing with marbles, that a remarkable change seemed to take place almost immediately in his mental apathy, and that he had not seemed as bright in many months.

Within the next few days the boy's mental condition changed still more wonderfolly for the better. He would enter my office with a laughing face, walk up to me, and shake hands without being told to do so; would talk to me about things he had seen, and showed the greatest interest concerning various instruments, etc., in my office.

He had had no convulsions for several consecutive days.

As I felt sure that (with the disappearance of atropine) the strong spherical glasses would be apt to cause the boy serious discomfort, and as no immediate prospect for further operative work seemed probable, I advised Dr. Stewart to take the boy home and to keep up instillation of atropine in the eyes at intervals, whenever the glasses caused the boy any discomfort. I also gave him a letter to an oculist near by in order that a specialist might make tests of the boy's eyes from time to time and inform me of his progress.

On the trip home, a report states that "the boy was so frolicsome and inquisitive on the train that he required constant supervision and care." The contrast was so great with his demeanor during his trip to New York as to excite the greatest surprise. No convulsions occurred during the trip.

A most pathetic scene occurred at the depot on the arrival of this boy, his mother becoming hysterical over what she termed "his resurrection to health and mind."

The following letter was received on August 14, 1893, from the oculist to whom he was referred by me: "Dear Dr. Ranney: You will be glad to hear that your patient, R. G., of Port Byron, has had no return of his epileptic attacks so far. His father reports him much less restless and better tempered. At the end of June, after the use of atropia for a week, I found 2.50 D. of hypermetropia, and consequently increased the strength of his glasses to +2.25 D. With these his  $V. = \frac{6}{5}$ ; there is esophoria of 2° or 3°, certainly not more; and abduction of 8°. The boy keeps his mouth open a good deal of the time, and I think possibly this and his decidedly 'weak' expression may be due to post-nasal adenoids. I propose to have this point settled when he comes to me next, which will be at the end of September. In the meantime there is no question as to the great improvement in his condition following immediately on the correction of his refraction and strabismus. I am yours very sincerely, F. W. Marlow."

During a personal interview with Dr. Stewart a few weeks ago (October, 1893), he said that the boy was working steadily on his father's farm, a source of income instead of a constant care as formerly. He also said that the father was very negligent in carrying out the instructions to have his boy wear the glasses constantly and have his eyes watched regularly, apparently being too ignorant to realize the importance of the matter, the gravity of the case, or the difficulties encountered in the treatment of epilepsy even under the most favorable anaptices.

As far as Dr. Stewart then knew, no epileptic seizures had occurred, but he expressed a fear that the negligence of the parents might create further seizures.

CASE IV.—Mr. H., aged forty-three years, merchant. Patient began to have severe epileptic fits when seventeen years of age. Had masturbated when a boy, and had been addicted in later years to excessive venery.

Family History.—One brother is a confirmed dipsomaniac; the father died of paralysis; one sister is a victim to sick headaches; no phthisis has existed in the family, so far as could be ascertained. History of the Case.—The epileptic seizures of this patient varied in frequency from two or three a week to one in three months. He came under my care in 1871 (when twenty-eight years old), and was treated by me for many years with enormous doses of the bromides of potassium and sodium. These salts reduced the attacks to about four a year. Stopping the bromides invariably increased the frequency of the attacks.

Eye Defects.—In January, 1886, his eyes were examined after his return from an extended residence in the South. He showed under atropine a latent hypermetropia of 2.50 D., and also a manifest esophoria of 4°. Subsequently several degrees of "latent" esophoria also became manifest. Abduction, 4°; adduction, 30°.

Treatment and Results.—Partial tenotomies were performed upon both interni, and hyperopic glasses, 2:50 D., were given him. Since the first operation (January, 1886) he has taken no bromides and has not had a convulsion. He has twice been at "death's door" with fevers, but he has shown at no time any epileptic tendencies.

I have not had an opportunity of examining the eyes of this patient for two years or more, but at the last test he showed an abduction of 8°, with \$6 vision in each eye, and an adduction of 45°. He was wearing his glasses constantly when I last met him (about two weeks since), and had been perfectly well for some seven years. He said that "he considered his epilepsy a thing of the past."

Case V.—Mr. H., aged twenty-four years, single, manufacturer. Referred to me by Dr. E. L. Mellus, of Worcester, Mass., March 18, 1890.

Family History.—Father has a nervous temperament; mother has gout severely and defective eyes; paternal grandfather died of bowel trouble; paternal grandmother died suddenly from some unknown cause; all paternal uncles and aunts, seven in number, lived to be from seventy-five to ninety years of age; maternal grandmother died of phthisis and insanity (after childbirth), and was nineteen years in an asylum; one of her sisters died of phthisis; one maternal aunt died of phthisis at sixteen years of age; maternal grandfather had gout terribly, drank heavily, and died of paralysis.

Eye Defects.—This patient showed an enormous amount of unilateral astigmatism in addition to marked heterophoria. Right eye + 0.50 c., axis  $90^\circ$ . Left eye + 4.00 c., axis  $180^\circ \bigcirc - 1.00$  c., axis  $90^\circ$ . Esophoria,  $11^\circ$ ; adduction,  $35^\circ$ ; abduction,  $3^\circ$ ; right sursumduction,  $4^\circ$ ; left sursumduction,  $4^\circ$ .

History of the Case.—Patient was perfectly healthy until he went to Exeter to fit for college. While in Exeter he had several epileptic seizures.

He had no special aura, but usually bit his tongue.

Had masturbated before his attacks, but has not since.

He then entered Harvard and stayed a year. He had, he thinks, four attacks during that year, during which he took no medicine.

He left Harvard in June, 1885, and in September, 1885, he went into the draughting rooms of his father's factory. For eighteen months he took no medicine, and in that time had several attacks.

While in Cuba in 1887 he had a very severe attack and began taking bromides. Within two months, while in Mexico, be had two serious attacks, cutting his chin badly in one and knocking out a front tooth in another.

He then came to New York and consulted an eminent neurologist, who increased his bromides and put him on restricted diet. He had only one severe attack and one of petit mal during the next year, but his mental condition became seriously impaired.

When he came to me his whole appearance and manner

showed markedly the poisonous effects of the bromides. His face was covered with acne. His mental condition was so bad that an interested conversation was almost impossible. In fact, it had become so alarming that his father, with tears in his eyes, said "that although he was his only son, he would rather see him dead than in his present position."

Treatment and Results.—All bromides were at once stopped. A full correction of his astignatism was given for constant wear, and graduated tenotomies were performed on both internal recti for the relief of his esophoria.

During the first six months of treatment, while his glasses were being changed and operations performed, he had five attacks—four very light ones and one medium attack. All of these occurred after excessive indulgence in rich and indigestible food late at night, and one after indulging in too much alcohol

During the next twenty months he had no attack of any kind. He had been actively engaged in business and has gained twenty pounds in weight. He had regained perfectly his mental condition; traveled without an attendant, maintained a yacht, and was considered perfectly well by his parents and physician.

Since June, 1892, patient has had no attack—a period of three years with only one slight seizure.

He has lately married, and has gained over twenty pounds in weight since he has abandoned bromides. His last tests showed the following conditions: Is wearing full correction for refractive errors, O. D.,  $\nabla$ . =  $\frac{20}{30}$ ; O. S.,  $\nabla$ . =  $\frac{20}{30}$ ; adduction, 38°; abduction, 6°; sursumduction—right, 4°+, left, 4°+; exophoria, 0.75°; left hyperphoria, 0.75°.

Case VI.—Mr. S., aged nineteen years. First seen by me on November 27, 1888.

Family History.—Mother has frequent and severe sick headaches, and her sister is a martyr to them also. The brother and sister of the patient have headaches. The paternal heredity could not be accurately given by the mother, who brought the boy to me for treatment. No phthisical tendencies had ever manifested themselves in any of the patient's ancestry, as far as known. Every known relative on the maternal side suffers from headache. The mother had very marked esophoria. She was treated by graduated tenotomies in my office with very great benefit. The cure of her headaches resulted. They had made her life a burden for years.

History of the Case.—The patient is a tall, finely developed young man of five feet ten inches, weighing about a hundred and fifty pounds, and with a good color. His mother gave the following facts:

Up to the fourteenth year of age the patient was in perfect health. He then had his first epileptic seizure, following upon an attack of so called "congestion of his brain," for which no cause could be found except a fall while skating. He was then at school in Paris.

Within the next year, in spite of bromides, he had three "fainting attacks," lasting an hour each.

He was then removed to a school in England, and had a number of severe epileptic seizures in spite of large doses of bromides.

In August, 1887, he was sent to America and placed in a select school, where he could be carefully watched over and his habits of life regulated. He had taken every day for the previous year not less than sixty grains of potassium bromide and fifteen grains of sodium bromide, and at times much larger doses.

During the year prior to his visit to my office the seizures had become more frequent and extremely violent—so violent that three men could not restrain the patient, and a room had been padded with mattresses and especially kept for the protection of the patient when thus seized. Into this room he would be placed and allowed to thrash about, until attack after attack would prostrate the patient. All medical treatment seemed of no avail, and the father was asked to remove the boy from the school.

Medical advice was then taken, and it was deemed advisable to commit the patient to an insane asylum as an incurable and uncontrollable case of dangerons epileptic seizures. At the earnest solicitation of friends, the parents were urged to make a trial of the "eye treatment" in the hope that it might possibly avert so horrible a fate for the boy, even if it did not markedly affect the frequency of the fits.

As the absolute cessation of the use of bromides was insisted upon by myself, from the date of the first visit, the boy was with some reluctance admitted at my solicitation to a private hospital, so that he could come to my office with an attendant and be protected from injury if the fits became very frequent or severe.

A record kept by the principal of the school showed that during thirty-four days fits had occurred in the twelve months that preceded my care of the boy, in spite of extreme doses of bromide salts and chloral at intervals in addition to his regular daily doses.

Eye Defects.—On the 17th of November, 1888, the patient showed normal vision in both eyes; adduction,  $5^{\circ}$ —; right sursumduction,  $2^{\circ}$ —; left sursumduction,  $2^{\circ}$ —; esophoria,  $2^{\circ}$ ; left hyperphoria,  $1^{\circ}$ .

In accommodation, patient showed esophoria 10°.

November 18th.—Under atropine, patient showed a latent hypermetropia of a scant one half dioptre. Esophoria, 2°; left hyperphoria, 0.5°.

Treatment and Results.—The patient carried his head, as his mother said he always had done, very markedly to the left side (justifying a suspicion that right hyperphoria actually existed), and his esophoria was very palpable to a careful observer. Later on, my suspicion of an existing right hyperphoria became confirmed by most positive tests.

Here, then, was a boy who showed at the onset almost perfectly constructed eyes, with only a slight tendency inward (apparently), and a suspicion of hyperphoria, yet he was having terrific epileptic seizures that were uncontrollable by drugs. His power of abduction was low, however, and prisms of 1°, base out, were placed for twenty-four hours over each eye.

At the third visit, on the following day, he showed esophoria of 7°; adduction, 71°; abduction, 3°; and the prisms were increased to 4°.

In three days more he showed esophoria of 10°, with unconquerable double images. Adduction 68°, and abduction 2°. The tendon of the right internal rectus muscle was freely relaxed by a graduated tenotomy. This improved his deviating tendency inward; but some esophoria still disclosed itself. Result: Esophoria, 2°; abduction, 7°; left byperphoria, 0°25°.

Subsequently a 2° esophoria prism was given the patient for constant wear. He disclosed at once 6° of esophoria, and his abduction fell to 4°; adduction, 73°.

On December 24th the opposite internal rectus was likewise operated upon, and his esophoria was apparently totally corrected for some time after the operation, his adduction being normal (8°).

On December 27, 1888 (ten days after the cessation of bromides), the patient had a fainting attack in my office without tremor, but with a total loss of consciousness for some ten minutes. The habit of carrying the head toward the left shoulder had been persistent up to this time. An examination of the eyes disclosed a right hyperphoria (as was originally suspected) of quite a high degree. From this date until February 12, 1889, patient was treated for hyperphoria by prismatic glasses, and no return of epileptic seizures had occurred. At this date the patient showed esophoria, 0°; right hyperphoria, 2°; adduction, 78°; abduction, 6°; right sursumduction, 4°+; left sursumduction, 0°. I then determined upon a third operation, and let out the right superior rectus as far as I deemed it wise to do so, although I apparently failed to correct his right hyperphoria by so doing. Results of operation: Esophoria, 0°; left hyperphoria, 0.5; right sursumduction, 3°-; left sursumduction, 2°+. Prismatic glasses, for a remaining tendency toward a right hyperphoria that soon disclosed itself, were again resorted to, as a step toward correction of the existing "eye-strain."

The boy then returned to his former school.

On July 1st, when the boy had passed over seven months without an epileptic seizure, I received a letter from his mother, from which I quote as follows:

"I want to tell you how very grateful I feel for the great good you have done my boy. It is really wonderful how he has improved in health since he has been under your care. He writes me that he has not had a single attack since I left New York. This seems almost a miracle when one remembers how the boy suffered before coming to you."

On July 7, 1889, over nine months had passed since an actual convulsion had occurred, and nearly eight months since the "fainting attack" in my office. He had been some time without prisms or any eye treatment, when he imprudently used a lawn mower violently on a very warm day for several hours. As a consequence, he was seized with one of his "old-time attacks," having three severe convulsions and two light ones in the next forty-eight hours. They were accompanied by marked gastric disturbance and fever.

July 10, 1889, on visiting me, I found over 2° of right hyperphoria for which I again operated upon the right superior rectus tendon. Tests after this operation showed no hyperphoria; esophoria, 1°; abduction, 6°; sursumduction—right, 3°; left, 3°—

On October 14, 1889, the patient engaged in a cross-country run of several miles, after school exercises, and became greatly overheated. He was again seized with a severe convulsion, and had two light ones later in the day. He had again marked gastric disturbance. Fourteen weeks had elapsed since the previous attack. An esophoria prism of 2° was given him.

On December 26, 1889, the patient was again seen. He had experienced no return of attacks, was in excellent health, and had taken no medicine for thirteen months. He still shows 1° of right hyperphoria, esophoria of 2°, adduction 58°, abduction 7°—, right sursumduction 4°, left sursumduction 1°+. He is wearing prismatic glasses for 2° of esophoria.

As operative work upon the eye muscles had been done somewhat rapidly upon this patient, he was allowed to wear his esophoria prism, with instructions to visit the office at intervals of a few days for the object of exercising the eye muscles by means of prisms and improving their tone.

Little change occurred. The old tendency toward right hyperphoria has never been disclosed, and gradually the right and left sursumduction have become equal. Some latent esophoria disclosed itself, however, and the abduction showed a marked decrease.

On October 29, 1890, the patient showed the following tests: Esophoria, 3°; left hyperphoria, 0°25°; adduction, 58°; abduction, 3°; sursumduction—right, 3°+; left, 3°—. He had been wearing a 2° esophoria prism.

A graduated tenotomy was performed on the right internal rectus. Result of operation: Esophoria, 0°; hyperphoria, 0°; abduction, 8°. On April 2, 1892, this patient had passed over ten months without an epileptic seizure, and only one attack had occurred in nearly two years. He is wearing now a 2° esophoria prism.

September 6, 1893.—Patient reported at the office after an absence of several months. He reported that he had discarded the 2° esophoria prisms that had been ordered for constant wear, and had been without them for several days, during which time he had been occupied in a hothouse. He was seized with a convulsion that asted some minutes.

Two years and three months had elapsed since his last epileptic seizure.

The tests of his eyes showed: Adduction, 45°; abduction, 5°+; sursumduction—right, 2°; left, 2°; esophoria, 2°; no hyperphoria; 2° esophoria prism was ordered.

November 12, 1893.—Since the last note the patient has had no epileptic seizure. His esophoria prism has been increased to 4°, as he has disclosed some latent esophoria. His last tests showed: Adduction, 69°; abduction, 3°; sursumduction—right, 2°; left, 2°; esophoria, 5°; no hyperphoria.

(To be concluded.)

# COMPLETE DESTRUCTION OF THE CONTENTS OF THE NASAL CAVITIES AS A RESULT OF SYPHILIS.

By JOHN DUNN, M.D.,

Mary S., aged twenty-three years. History as follows: Patient is about four feet ten inches tall; mulatto; sickly as a child. At an early age had some skin eruption, whose nature she does not know; at the age of five or six had a deep sore on the back of her leg, difficult to heal; at fifteen had some "private trouble"; at sixteen had "scrotulous glands in the neck" and "sore eyes"; was "blind for a while"; at eighteen had a "sore eyes"; was "blind for a while"; at eighteen had a "sore throat," which left her with "that hole in the palate"; at twenty her nose began to annoy her and her eyelids to swell; at twenty-one "the last piece of bone came out of the nose," and she began to get well; is the mother of two children. Such is the history of the case, the condition of whose nasal cavity is here to be briefly described.

The dorsum of the nose is flat, giving the patient the appearance of having epicanthus; the alæ are both drawn in toward the nasal cavity, the right ala being the more depressed of the two. The interior of the nose has been deserted by its every inhabitant. There is to be seen no trace of sæptum, bony or cartilaginous, from the cribriform plate to the floor of the nose. Even the intermaxillary crests appear to have been destroyed. The floor of the nose is level, except in the middle line posteriorly, where appears a small teat about two millimetres in diameter. There is no trace on either side of inferior turbinate, which, with lacrymal, ethmoidal, and maxillary processes, have been entirely destroyed. There is no sign of an ethmoid bone, of middle or superior turbinate, of ethmoidal cells, anterior or posterior, of unciform process. The maxillary sinus on either side is a continuation of the nasal cavity. All is one huge chamber, whose two sides are symmetrical and whose boundary lines have been destroyed. The nasal cavity passes into Highmore's antrum on one level, whatever of bony partition once existed having been destroyed. High up on either side of this now nasal cavity, somewhat back, can be seen two round holes, about two millimetres in diameter, the inferior terminations of the once ethmo frontal canals. (These are stopped up with thick mucus.) Centrally, behind, in the extreme upper part of the pasal cavity there is an elliptical opening, of which the long diameter is about four or five millimetres. The mucous membrane overlaps this pit, which, I suppose, represents the opening into the sphenoidal sinuses, into which, however, I was unable to probe. Posteriorly below, in the region of the soft palate and Eustachian tube, the tissues are all drawn together, so that when the patient swallows, this region resembles somewhat the puckered opening of the ordinary rubber tobacco bag. The Eustachiantube mouths have been much injured by ulceration, are grown to the soft palate, and their openings are represented by narrow slits which can be seen by anterior rhinoscopy. The patient's hearing is excellent. The sense of smell is, of course, destroyed, The mucous membrane of the nose is fairly normal in appearance, is smooth save for the above-mentioned openings, and the secretions, while more than normal, are not excessive, nor does there seem to be an undue tendency to the formation of scabs. When the patient opens her mouth a triangular hole can be seen in the soft palate just above the uvula, which is elongated. The patient has never had, to her knowledge, since infancy any skin eruption. Treatment I have been unable to find out. It is fair to infer, however, that it must have been almost altogether neglected.

Many interesting questions are suggested by the abovedescribed case, but, as only the result of the inflammation was seen, the case is reported as a result, without comments.

# A BRIEF SYNOPSIS OF THE THERAPEUTICS OF STATIC ELECTRICITY.

By S. H. MONELL, M. D.

With a view to present the recognized indications for static electricity in a form appropriate for ready reference, the following paper is submitted by the author. To those already familiar with the well-known properties of the galvanic and faradaic currents, the tabulated statement herein offered will furnish a convenient means of comparison. No attempt will be made to specify the various methods of administration, it being assumed that the reader is acquainted with the technique of operating the static machine. The writer's system of interrupting the static current has been described in other articles and to them the reader is referred. The sphere of therapeutic action of static electricity is sufficiently wide to be justly considered remarkable without proclaiming it a cure-all. In many acute inflammatory states there are other agents which will generally be called into use, yet even here there is some work which "static" can well do. Its chief field, however, is found in conditions, either acute or chronic, which have to do with nerve action, muscles and joints, pain, functional processes, and nutrition.

- (a) It affords the most certain and permanent relief for lumbago, sciatica, rheumatic and muscular pains.
- (b) Neuralgias of every kind seem to yield to it more speedily and permanently than to any other form of treatment. In the various types of head pains and in insomnia it is peculiarly efficacious.
- (c) No other agent equals static electricity in combating hysterical states and associated conditions. It furnishes our best method of treating functional nervous diseases.

- (d) It is an efficient regulator of deranged bodily functions and is not surpassed by any other agent in the successful treatment of that important class of ailments known as functional diseases.
- (e) As a general tonic and as a stimulant to depressed nervous functions it is of the utmost service, especially in neurasthenia and in old cachexias. As a means of improving the general nervous tone of patients it is without a rival.
- (f) Reflex irritation, peripheral neuroses, etc., yield in most cases to proper applications of this agent. Pruritus of various forms, the itching of eczema, etc., are cases in point.
- (g) In all dietetic diseases it acts with decided benefit; it produces remarkable improvement in disturbed visceral functions, nausea, vertigo, dyspepsia, constipation, colic, etc. In chlorosis and anæmia and all perversions of nutritive processes it lends ready aid to the restoration of the normal functions.
- (h) Diseases of the scalp. Patients undergoing several months of regular static treatment usually find that their hair ceases to fall out in combing and that the nutrition of the scalp improves.
- (i) Exudations, infiltrations, localized edemas, etc., are quickly resolved and absorbed under skillful static administration.
- (j) It usually surpasses all other forms of electricity in dealing with stiffened, contracted, or paralytic muscles, acute or chronic muscular deformities, and muscular spasm. The ease with which it will often conquer an obstinate case is one of the most surprising things in electro-therapeutics. Acute examples of these types not infrequently succumb to one or two séances of static.
- (k) Its tonic action makes it a valuable agent in diseases of the heart, both functional and organic. Where coldness of the extremities or general want of vital warmth exists it possesses a singular power to promote the creation and distribution of animal heat.
- (1) In locomotor ataxia it will do more to relieve pain and maintain a degree of comfort than any other agent. Used in conjunction with galvanism, it may arrest the progress of early cases indefinitely.
- (m) It has given the most brilliant results in the treatment of hemiplegic, traumatic, and all forms of motor paralysis, and frequently restores complete muscular power after all other measures fail. Paralysis of the sphincters, of the vocal apparatus, or of any part of the body may be treated with better success by static than by other measures.
- (n) It admittedly holds the highest place in the treatment of chorea.
- (o) In epilepsy it produces excellent results in improving the general condition and in moderating the frequency and the severity of the attacks.
- (p) In mental disturbances it should be faithfully tried whenever possible.
- (q) Disorders of sensation are more rapidly improved by static electricity than by either galvanic or faradaic applications.

- (r) In exophthalmic goitre it affords relief to some of the most distressing symptoms.
- (s) In gout and rheumatism its efficiency has been reputed great since the earliest history of frictional machines; even in rheumatoid arthritis it has won praises.
- (t) It is a powerful, painless, and effective tonic to the weakened muscles in lateral curvature of the spine; as a "massage" it is unequaled.
- (u) In the treatment of chronic inflammatory and spasmodic diseases—such as influenza, phthisis, bronchitis, unresolved pneumonia, asthma, laryngitis, neuritis, synovitis, etc.—it gives excellent and often brilliant results.
- (v) In dermatoses, especially those dependent for their origin upon neurotic or nutritional disturbances, it is either an all-sufficient remedy or a valuable adjunct to medicinal measures.
- (w) In gynæcology the static machine furnishes most valuable auxiliary aid to galvanism, and single-handed will conquer a large percentage of woman's troubles.
- (x) In convalescence from acute disease, debilitating fevers, and in all the tedious, irksome conditions of a slow recovery from an exhausting illness, the tonic and vitalizing action of static electricity excels any other agent in the author's experience.
- (y) It is an invaluable tonic for the general infirmities of old age. Its constitutional effects increase the sum of vitality and it will do much to relieve the distressing symptoms which render declining years a burden and a care.
- (z) No other electrical application may be made so gratifying to the patient; no other method of treatment elicits such frequent expressions of satisfaction; no remedy may be more swift and permanent in action; none may be more easily applied in many cases.

This list does not exhaust its powers of usefulness, but will point the way to its application in various obscure conditions where diagnosis is difficult and where past treatment has yielded poor results. In these anomalous cases great aid may not infrequently be obtained from skillfully directed static electricity. Nearly every possible application of faradism can be duplicated with "static," and the full limit of its many-sided capabilities probably lies far beyond our present knowledge and experience. That it can promptly remove all pain and soreness from a superficial burn I recently demonstrated to the satisfaction of a careless assistant who had come in too close contact with a gas heater in my office. Its control over nerve and muscle functions borders upon the phenomenal. Considered from every standpoint, a successfully operated and powerful static machine is, without doubt, the most surprising single therapeutic weapon in the whole arsenal of scientific medicine. Even with its infirmities it is marvelous, and if ever perfected it will be invincible in popular

Note.—Since I wrote this article an improved static machine has been placed before the profession by the Galvano-Faradic Manufacturing Company which appears destined to greatly extend the therapeutic value of this form of electrical administration.—AUTHOR.

# NEW YORK MEDICAL JOURNAL, A Weekly Review of Medicine.

Published by D. Appleton & Co Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 20, 1894.

#### "KOSHER" MEAT AND EFFICIENT MEAT INSPECTION.

THE British Medical Journal for December 23d has a leading article on the advantages and disadvantages of "kosher" meat, in connection with a lesson concerning food production taught by a recent ordinance adopted by the town of Carlisle. The corporate authorities of that city have been enabled to suppress places of private slaughtering, small and irresponsible concerns chiefly. All the animals are there slain in central abattoirs under the inspection of city officials whose duty it is to prevent cruelty and to detect diseased conditions of the animals and meat. London now has five hundred and thirty-seven private slaughterhouses, but the number is rapidly diminishing. These houses are only partially supervised, for there is no systematic inspection of the slain animal except in the Jewish places. In Gentile places there is no legally prescribed method of slaughter; the animal may be pithed, stuck, shot, or beheaded. The "schochet," as the Jewish slaughterer is called, in obedience to the ritual of the Hebrews, kills the animal by the process of bleeding, and the creature must of necessity endure a comparatively long period of intense suffering-passing through terror, psin, faintness, and epileptic convulsions. The Jewish slayer has this superiority over the Gentile, that he can not enter upon his vocation unless he has successfully passed his examinations before a board of Jewish experts in all matters relating to "schecheta," or slaying. He must know the signs of disease in the animal and of unwholesomeness in the flesh. Meat that is without blemish is marked with a seal telling in Hebrew characters the name of the sealer and the date of slaughter. Such sound meat may become the food of the orthodox Jews, and is known as "kosher," while meat that is not "kosher" is sent to the markets of the Gentiles. From reports made by the Jewish slaughterers at Deptford and other places in East-London it appears that only seventy-three per cent. of ox and sheep meat that was inspected at those places yielded "kosher"; the remaining twenty seven per cent. presumably went into the markets where the East End artisans purchase their food. The writer estimates that not less than ten per cent. of the meat annually sold-about two hundred and twelve thousand tons, according to the totals reported for the year 1892 by the Board of Agriculture-was positively unsound or unwholesome.

The remedy, needed by London and many other large cities, according to the writer, is to concentrate the slaughtering places into public abattoirs, in which it will be possible to carry out a system of continuous inspections by skilled men. With the slaughterhouses widely scattered, a satisfactory inspection could only be effected by a vast army of inspectors, maintained

at an enormous expense. And even then there would be room for doubt as to the possibility of an evasion of the authority of the officials, whenever the latter are absent. At present the presumption is that "only a small portion of unfit meat is detected and destroyed, and a still smaller fraction of needless cruelty is prevented."

In the January issue of Public Health, J. Lawrence Hamilton, M. R. C. S., reprobates the Jewish method of slaughtering. He is himself a Jew—presumably of the non-orthodox branch—and has had opportunities to inspect the work done in the Jewish slaughterhouses personally. He condemns the Jewish method of killing cattle as "consummately cruel and clumsy"; the meat is prone to decomposition and does not keep fresh so long as so-called "Christian" meat. He quotes Sir Benjamin W. Richardson as saying that less blood is retained in the flesh of an ox killed properly by the pole-axe than in that of an animal put to death according to the Jewish ritual.

Of the Jewish system of meat inspection Mr. Hamilton states bluntly that it is a farce, for the reason that the inspectors are ignorant of veterinary science and the use of the microscope. He further shows that in several European countries, as in Saxony, in Switzerland, and in the city of Berlin, there have been public agitations against the "cutthroat method" of killing cattle as being needlessly cruel and revolting. He has, watch in hand, timed the duration of the dying process after Jewish slaughter, and he has known seven minutes to be occupied. Dr. Richardson has alleged that as much as twenty minutes may elapse in that process.

## MINOR PARAGRAPHS.

## ANTIDIPHTHERIN.

A THERAPEUTIC note in the British Medical Journal for December 30, 1893, cites the experience of Kunne, of Vienna, in the use of Klebs's antidiphtherin. Four cases of diphtheria were treated; of these, two were in children admitted into a hospital with moderately high fever and slight membranous exudation on the tonsils. Applications of a five-per-cent, solution of the new drug were at once made, and repeated three or four times in twenty-four hours. On the following day the fever had subsided and the membrane had disappeared. In a third case the disease was very severe, and there was an extensive growth of the membrane. Tracheotomy was necessary. The applications of antidiphtherin in this instance-a one-percent. solution-could only be made through the tracheotomy tube. They appeared to be without effect; the child died by an extension of the disease into the bronchial tubes. In the fourth case the treatment seemed to have a favorable effect at first; the fever was reduced and the membranes became disintegrated, but their formation anew was not prevented. In this case the remedy probably had no particular effect.

### A JUDICIAL DOGBERRY.

UNDER this title there appeared an article in the Journal of the American Medical Association for December 23, 1893, containing a report of the case of a Dr. Gibbs, of Omaha, who was fined by a judge for being absent from the court room when he had been subpoenced as a witness. The doctor pleaded in extenuation that he had been called to attend a patient who was

very ill, and had not been able to reach the court room at the time. The judge asserted that the doctor should have notified the court, as the case was on trial, and, refusing to accept his excuse, fined him ten dollars. It is well for physicians to know exactly what position they hold, if the dignity of the law is to be upheld at any cost, without regard to the conditions of patients. A case in point was one of obstetrics which was unexpected, and the call for the doctor came a few minutes before he was to leave for the court. As it was in the country, it was impossible for a messenger to be found and sent, so the doctor was obliged to commend the care of the patient to some neighborly women until an excuse was obtained from the court. On his return he found that the case had passed into other hands, and, besides losing his patient, he was severely censured by persons who did not understand the situation. Innumerable emergencies might arise where a conscientious physician would see that his paramount duty was to his patient, and yet it might be impossible to notify the court at the time.

#### LA GRIPPE.

A PHYSICIAN who has just passed through an attack of this distressing disease thus writes to a friend: "Did you ever have this infernal disease that they call the grippe? If not, don't. I have been through it for the last six weeks and am ready to give my friends the benefit of my experience. It is certainly the most diabolical malady that ever got out of Pandora's box. If the old girl has anything worse in reserve I trust she will keep the lid of her Saratoga safely locked and then kindly sit on it. Sneeze, freeze to death, burn up, have your energy sapped, let all the clouds of heaven lower over your head, get on familiar terms with all the blue devils that ever escaped by volcanic exit from equatorial eternity—do all of this and keep it up for six weeks, and then you can intelligently listen to a lecture on la grippe. Cerebration becomes altogether of the too conscious sort for literary work."

#### PELLAGRA.

The Prager medicinische Wochenschrift contains an article on this disease by Dr. Tuczek. It was through a study of the possible relation between ergotism and dementia paralytica among the Italians that the author was brought to notice the apparent association of pellagra. Histological examinations of the nervous system, in cases where death had ensued, with pellagra present, showed marked degenerative changes in the spinal cord, especially in the posterior and lateral columns. The author believes that his studies are sufficiently confirmative to warrant the statement that the poison from the diseased grain acts in such a manner upon the nervous system as to produce degenerative changes in the spinal cord, and that an important addition is thereby made to our knowledge of the attology of nervous diseases.

## THE NEW YORK CITY HEALTH DEPARTMENT.

Having recently had occasion to visit several of the offices of the department, we have a very profound impression that the medical officers and laboratory workers have been wofully handicapped in recent years by their limited accommodations and wide separation from each other. We judge that the department had outgrown its rooms and conveniences fully five years ago; there are several offices of the first importance that derive their light and air from contracted air-shafts. But a better condition of affairs is very soon to be brought about, for

even now the employees of the department are busily engaged in preparing for removal to better quarters in the new municipal building on Centre Street.

#### THE PARIS CHOLERA CONFERENCE.

The President has appointed Dr. Stephen Smith, of New York, Dr. Edward O. Shakespeare, of Philadelphia, and Dr. Preston H. Bailhache, of the Marine-Hospital Service, as delegates to the approaching Paris conference regarding the international relations of Asiatic cholera. This movement is under the auspices of the French Government, and is spoken of as the International Sanitary Commission of 1894. Each of the great powers of the civilized world has received an invitation to be represented by three delegates. The first session will be held on January 24th.

#### A PROPOSED MEDICAL CONGRESS IN ASIA,

The Indian Medical Gazette suggests that the time has come for a medical meeting for India and the tropical sections of southern Asia. The Gazette states that the conditions which surround professional work in the tropics have received slight attention in the deliberations of the medical congresses held in colder climates. Tropical diseases and tropical sanitation, it says, are subjects that would especially be proper for discussion in a convention at Calcutta or Madras.

#### DISINFECTION ON LONG ISLAND.

The Independent reprints literatim et punctuatim the following paragraph from a board-of-health report of a town on Long Island: "Every person who is confined in a house owing to sickness and contagious diseases, should at all times be thoroughly covered with disinfectants both externally and internally, to insure safety to themselves and others as in my mind a spread of the same is caused by carelessness on the part of people who know it all and can not be told by persons of experience."

#### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 16, 1894:

DISEASES.	Week end	ing Jan. 9.	Week ending Jan. 16.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	0	0
Typhoid fever	10	5	6	1
Scarlet fever	96	11	113	13
Cerebro-spinal meningitis	1	2	0	0
Measles	491	29	473	24
Diphtheria	229	55	187	52
Small-pox		2	18	2

The New York Ophthalmological Society.—At the annual meeting, held on Monday, January 8th, the following officers were elected: President, Dr. W. S. Dennett; vice-president, Dr. Frank N. Lewis; secretary and treasurer, Dr. D. W. Hunter; committee on admissions, Dr. Henry D. Noyes, Dr. Arthur Mathewson, and Dr. J. B. Emerson.

The Medical Society of the Northern Dispensary.—The special order for the last meeting, on Wednesday evening, the 17th inst., was a paper on Aphtha and Diphtheria; their Association and Differentiation, by Dr. Adolph Rupp.

The Kings County Medical Association.—At the recent annual meeting the following officers were elected: Dr. T. M. Rochester, president; Dr. N. W. Leighton, vice-president; Dr. Raynor and Dr. Riggs, secretaries; Dr. E. H. Squibb, treasurer; and Dr. R. M. Wyckoff, member of the executive committee.

The late Dr. O. G. Harrison.—A respected member of the faculty of the New York College of Pharmacy has sent us the following:

"The New York College of Pharmacy suffers a severe loss in the person of Dr. O. G. Harrison, instructor in botany, pharmacognosy, and materia medica, who died very unexpectedly, after a short illness, on the evening of Sunday, January 14th. He was taken ill on the preceding Tuesday with severe abdominal symptoms, from which he afterward partially recovered. The nature of his disease could not be determined until Sunday morning, when the indications of intestinal rupture became unmistakable, and an operation was at once performed. A successful result was, however, quite hopeless, and the doctor died at half past nine the same evening. He was conscious almost throughout, and was perfectly calm and ready for death.

"Dr. Harrison was an able scholar, both at the College of Pharmacy, where he was graduated in 1890, and at the College of Physicians and Surgeons, where he was graduated in 1891. In order to fit himself more particularly for pursuing the study of the structure of drugs, he worked assiduously at histology during the past summer, under Professor Penhallow, at the Harvard Summer School of Science. In addition to his position at the College of Pharmacy, Dr. Harrison was the highly appreciated assistant of Dr. R. W. Wilcox at the Postgraduate Medical School, a member of the New York City Board of Pharmacy, and the editor of the Journal of the Alumni Association, C. P. C. N. Y., the first number of which was just about to be published. His untimely death, just when the increasing prosperity of his college seemed about to usher him into a brilliant career in his chosen line of work, must appear exceptionally hard to his relatives and friends, particularly to his young widow, to whom he was married less than a year since. As a son and husband, Dr. Harrison appeared to have approached about as near as possible to the ideal. His character as a man was singularly modest and quiet, yet dignified and strong, and he was a Christian of the sort to make even the fixed unbeliever pause and wonder if, after all, there was not something distinctive in the Christian character."

The Death of Dr. Frank Dudley Beane, of New York, occurred in Riviera, Florida, on Saturday, the 6th inst. He had been the subject of some pulmonary disease and had been advised to go to Florida, where he was taken dangerously ill with symptoms pointing to cerebral congestion. He was born in Manchester, New Hampshire, and was forty-two years old at the time of his death. He was a graduate of Bellevue Hospital Medical College, of the class of 1872. He was connected with the New York Eye and Ear Infirmary for a number of years. Dr. Beane was highly respected by his professional brethren.

The Death of Professor Rudolph Kaltenbach is announced. He was professor of gynæcology in the University of Halle, where he succeeded Olshausen in 1887. In 1867 he became the assistant of Hegar, then at Freiburg, and the two worked together as clinicians and authors for many years. He went from Freiburg to Giessen in 1888. His Lehrbuch der Geburtshülfe, published in 1893, is a work very highly esteemed in Germany.

## Society Meetings for the Coming Week:

MONDAY, January 22d: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, January 23d: New York Dermatological Society (private); Buffalo Obstetrical Society; Medical Society of

the County of Putnam (semi-annual), N. Y.

Wednesday, January 24th: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private); Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society.

THURSDAY, January 25th: New York Academy of Medicine (Section in Obstetrics and Gynaecology); New York Orthopædic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

FRIDAY, January 26th: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, January 27th: New York Medical and Surgical Society (private).

# Retters to the Editor.

POISONING WITH BISMUTH.

ELIZABETH, N. J., January 5, 1894.

To the Editor of the New York Medical Journal:

Sir: In reading the extract from the Lancet in your issue of December 30, 1893, on Bismuth as a Local Application in Burns, my mind went back to a case of bismuth poisoning which came under the notice of our hospital staff during the month of June, 1892. Thinking it may be of value to the profession to record such a case, I take the following from the records of the Elizabeth General Hospital: A German girl, fifteen years old, single, brunette, and of a nervous temperament, received a burn of the third degree, covering an area of sixteen by fifteen inches, on her back. This occurred on April 16th. She was admitted into the hospital on June 2d. From the time of the accident until her admission she had been treated by a physician, and we know little or nothing of the treatment. Upon her arrival she was anæsthetized with ether and the burned surface scraped and cleansed with a 1-to-3,000 bichloride of-mercury solution and dressed with bismuth subnitrate (Squibb's); over this were placed muslin, cotton, and a band-

The patient was placed upon the use of a milk diet and the wound dressed every second day. This treatment was continued until June 10th, when the dressing was discontinued, the following signs and symptoms having been discovered: A black line along the margin of the gums, involving those of both the upper and the lower jaws; headache, nausea, vomiting, paleness of the countenance, a urinous odor of the breath, elevated temperature, increased rapidity of the pulse, and increased frequency of micturition. The urine was light in color, having a specific gravity of 1 ol2, and acid in reaction, and contained a small amount of albumin.

Œdema and pain of the lower extremities and some cutaneous irritation of the upper limbs, with a marked diarrhœa, ex-

isted and continued until her death, which occurred on the 18th of June.

The literature on this subject seems to be meager, but I feel convinced, as do also my coworkers, that this was a genuine case of bismuth poisoning. The bismuth was tested for lead and arsenic, and both were found to be absent.

NORTON L. WILSON, M. D.

# Proceedings of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of January 2, 1894.

The President, Dr. M. Allen Starr, in the Chair.

Traumatic Deafness .- Dr. J. LEONARD CORNING DARRATED the history of the following case: The patient was a lad eighteen years old, who had received a severe kick directly over the right ear while engaged in a game of football. He was first seen by Dr. David Webster, who, upon careful examination, found that there was total deafness on the right side; aerial and bone conduction were suspended. There was no trouble of the middle ear, and the drum was in perfect condition. There was slight bleeding from the external ear. There was no evidence of fracture. The case was then referred to the speaker, who applied to the ear a rapidly interrupted faradaic current, which was allowed to pass through the ear for about ten minutes, when the hearing was so far restored that the patient could hear the watch at a distance of six inches. Before making the application, the external meatus was plugged with absorbent cotton moistened in salt solution. A severe tinnitus, which existed with the deafness, was also relieved. The speaker said he had no idea of what the lesion had been or why improvement had followed the use of the current; it had been employed simply as a tentative measure. The young man's hearing was now entirely restored. There was no suspicion of hysteria. The visual field had not been tested.

Dr. David Webster said he supposed the deafness had been due to concussion either of the auditory nerve or of the labyrinth, of which he had seen cases reported. Temporary blindness had been produced by a sudden blow on the brow, without ophthalmoscopic or other lesion. Most of those cases, however, were due to fracture of the base of the skall involving the optic foramen and producing nerve atrophy. He had never seen another case similar to the one reported by Dr. Corning.

The President suggested that the case might have been one of traumatic hysteria or concussion of the auditory nerve. In consultation with Dr. Jacoby he had recently seen a case of total deafness in both ears of central origin in which a temporary improvement in the hearing had been produced by the use of a strong galvanic current, about six milliampères, which was a strong current for the acoustic nerve.

Dr. J. Arthur Booth said that in a number of cases of tinnius he had employed the galvanic current with marked benefit. He had never seen a case similar to the one reported by Dr. Corning.

Acromegaly.—Dr. RALPH L. Parsons reported the case of a man aged thirty-six years, whose family history was negative, and who had never had veneral disease or used alcoholic stimulants. He had been in good health until eighteen years ago, when he had had an attack of malarial fever. From this he had recovered and had had no recurrence since. Ten years ago he had been told that he stooped and carried his head to

one side. Eight years ago he had begun to suffer from a pain in the back of his head. This came on mostly at night, and not oftener than once a week. Subsequently the headaches occurred more by day than by night. Latterly they had increased in frequency and duration, and had often been excruciating in character. The pain was usually most severe at the occiput, but would also involve the left parietal and frontal regions; the right side of the head was unaffected. About six years ago his attention had been first called to the large size of his hands. He then for the first time perceived that they were of extraordinary size. He did not know for how long a time this increase in size had been taking place. He could not say whether they had increased in size during the past preceding six years.

A careful examination of the patient had been made in October last, with the following result: Weight, two hundred and twenty-seven pounds. No pronounced symptoms of organic disease. Hair rather coarse, but natural in condition. Left ear slightly thickened. Forehead retreating; superciliary ridges quite prominent; no exophthalmia; malar bones rather prominent; cheeks rather sunken; nose broad and full at the nostrils; lips normal; tongue decidedly enlarged, obstructing free articulation; alveolar processes normal; teeth not separated; chin elongated; head inclined strongly and habitually to the left side and forward; hands large and spadelike, the right hand being decidedly the larger. The soft tissues of the hands and fingers were firm and resilient, as though infiltrated by an elastic substance; they did not pit on pressure. Wrists rather large; arms normal; thorax and pelvis normal. The feet were large, but perhaps not larger than in the case of many men of his weight. The patient had perspired very freely for the past ten years; of late the perspiration had been decidedly offensive. Besides the headaches already referred to, the patient also complained of pain in the left ear and eye, the latter coming on after reading or using the eye in a strong light. He did not think his evesight had become impaired. The appetite and thirst were excessive, and there were no marked mental symptoms.

On the 21st of October last, by advice of Dr. Starr, the patient began the use of thyreoid extract, five drops three times daily. The dose was gradually increased until he had received fifteen drops three times daily. With the exception of tonic baths, general hygienic measures, and a regulation of the diet, no other treatment was given. At the present time the patient reported that he was feeling decidedly better; he was more cheerful and his headaches had been relieved to a very great extent. They had not, however, entirely disappeared. There seemed to be no change in the dimensions of the hands. His weight had increased rather than diminished. There had been a great improvement in the subjective symptoms, but there was still a reasonable doubt whether this improvement was due to the direct action of the medicine, or to the patient's mental status induced by the fact that something was being done for his relief.

Dr. Corning was inclined to think that the improvement in the condition of the patient had been due to the medication employed, rather than to the mere fact that something was being done for him. Such patients, he thought, were usually not of a very imaginative turn of mind.

Dr. Webster inquired whether any change in the thyreoid gland had been noticed in the case, also whether there was any relationship between acromegaly and myxædema.

The President said he had been somewhat responsible for the use of the thyreoid extract in the case narrated by Dr. Parsons. There had been nothing original in the suggestion, as this method of treatment had been pursued in England, in a number of cases of acromegaly. It was purely empirical. The supposed lesion of acromegaly was an increase in the size of the pituitary body. It was questionable whether it was in any way related to the thyreoid gland. The eye symptoms in Dr. Parson's case had interested him, because in two other cases of acromegaly coming under his observation there had been a concentric diminution of the visual field, and in one hemianopsia; the latter symptom was quite common, and was probably due to pressure on the chiasm by the enlarged pituitary body. In one case of acromegaly seen at St. Luke's Hospital last spring the patient had died of pneumonia, and at the autopsy the pituitary body had been found to be normal. There had been nothing to account for the peculiar growth of the bones.

Dr. Parsons, in reply to Dr. Webster, said it was generally supposed that there was a sort of relationship between acromegaly and myxedema; whether this belief was well founded, or what that relationship was, he did not know. While his patient was not of an imaginative turn of mind, still he was hopeful, and that element would influence his mental state and perhaps even improve his physical condition.

Some Less Cultivated Phases of Psychology: Considerations of the Genesis of the Feelings, or the Relation of Desire to the Will Function; Practical Deductions therefrom concerning the Management of Various Psychopathic Conditions,-Dr. J. Corning read an interesting paper on this subject, in which he traced the relationship of the desires to the function of the will, and showed the importance of psychical influences in the correction of certain morbid mental conditions. In neurasthenia, simple melancholia, hysteria, and other functional nervous troubles the desires were best evoked and fostered through the special senses, notably through the sight and hearing, while at the same time the receptivity of the sensorium was increased by proper stimulation. The effect thus gained was not necessarily evanescent. Due heed should also be given to the general bodily condition. Nutrition must be improved and gouty and other morbid tendencies antagonized. The question of influencing the mind to the profit of the patient was certainly an important problem in neurology, and one well worthy of discussion. In concluding his paper, Dr. Corning referred to the loss of prestige which had apparently overtaken hypnotism, and which in too many instances only served to substitute a veritable neurosis for the morbid condition which it was sought to modify.

Dr. W. H. Thomson said that his own plan in the treatment of melancholia had been not to appeal to the will of the patients at all; it was only discouraging to them to tell them to think less of their condition; their train of thoughts should be involuntarily changed by new objects brought to their senses, either through the eye or through the ear. By means of a change—using the word in its broadest sense—a change of scene, of surroundings, and of society, we should endeavor to produce an involuntary displacement of the morbid ideas.

Dr. Parsons said that while, in his opinion, the principal means we had of influencing the mental state were by a correction of the bodily conditions and habits, change of surroundings, etc., yet the suggestions made by Dr. Corning were of value in certain cases, especially when the person who gave the advice was capable of exerting a strong personal influence over the patient.

Dr. William A. Macy said the suggestions made by Dr. Corning were of value in certain cases, such as mild forms of melancholia, where the patients were still able to be controlled or influenced by the suggestions of others. After the patient had progressed beyond this stage and had delusions, comparatively little could be done for him in this way. In the early stages of functional nervous trouble, suggestions, encourage-

ment, change of scene, etc., were everything to the patients; they were even more important than medicines.

Dr. E. D. Fisher said that Dr. Corning's suggestions probably referred to the functional rather than to the organic nervous diseases. There was no doubt that the minds of these patients could be influenced by suggesting pleasant ideas, or bringing new scenes before them. This required training and discipline. In all forms of nervous diseases the emotional state was the one first affected, and it was in this stage that the suggestions made by Dr. Corning were likely to prove of service.

Dr. Corning said that in his paper he had referred to functional cases. Most of the organic cases were not amenable to any form of treatment. His object in bringing up this subject had been to show that something could be done to modify the mental state of the patient; it could be relied upon entirely, but should be combined with proper medication, with stimulants dexterously given, with supernutrition, rest, etc., as any or all of these were indicated. In this way we might prevent a melancholiac from going from bad to worse if there was no organic trouble behind the functional disturbance.

Ergot in the Treatment of Periodical Neuralgias.—Dr. WILLIAM H. THOMSON read a paper on this subject, in which he gave the histories of a number of cases of severe periodical neuralgias in which the symptoms had been promptly relieved by the use of ergot in large doses. In all of these cases the disease had been of long standing, and the usual remedies had been employed without avail. Dr. Thomson said his method of administering the ergot in migraine was as follows: The fluid extract of the drug was employed, combined with an equal quantity of elixir of cinchona, to obviate its tendency to cause nausea. Two drachms of this mixture were to be taken in water as soon as the premonitory symptoms of the headache were noticed, and the patient was advised to lie down and keep very quiet. If, after an hour, the headache continued, a second similar dose was taken, and then a third in another hour if necessary. As nausea was such a general accompaniment of this affection, it was provided that if either of the doses be vomited it should then be taken in an enema of two ounces of water. This medication, the speaker said, rarely failed to arrest the attacks, even in long standing cases, and with a preventive course of intestinal antisepsis in the intervals the relief from the malady had often proved permanent. The following was the history of one of the cases reported by Dr. Thomson: The patient was a young man who suffered from headaches beginning at the occiput and extending to the temples; they generally came on about 11 A. M. daily, and gradually grew worse until they reached their acme, about four o'clock in the afternoon, after which they subsided, without, however, entirely disappearing. His physician had failed to check their increasing severity, although on one occasion he had administered thirty-grain doses of chloral with thirty grains of potassium bromide every two hours until two doses had been taken, with little more effect than a slight drowsiness being produced. The next day, the patient becoming maniacal from the pain, sixtyfive grains of chloral, sixty of bromide, and thirty of antipyrine had been given within two hours. This had caused a profuse sweating and moderate sleep. The third day a consultant had been called, who recommended that quinine and Warburg's tincture (which had been tried at the beginning of the treatment) should be resumed in large doses. Accordingly, sixty grains of quinine and two ounces of Warburg's tincture had been given in twenty-four hours, with even worse afternoon paroxysms of pain than before. The next day the bromide, antipyrine, and chloral had been resumed, but no great relief had been obtained. At this time he had been seen by Dr. Thomson, who recommended drachm doses of the fluid extract

of ergot every hour until three doses were taken, the first two doses being combined with ten grains of quinine, and if his stomach rejected either of the doses, the medicine was to be given per rectum. Soon after taking the first dose the patient experienced a good deal of relief; the second dose had been vomited, whereupon it had been given per rectum, and this had soon been followed by a complete subsidence of the pain, with profuse perspiration. This medication was repeated for three successive days, with final cure of the headaches. The second ten grains of quinine produced decided symptoms of cinchonism.

Dr. Joseph Collins said he had before heard Dr. Thomson recommend ergot in the treatment of periodical neuralgias, and had recently had occasion to try it in several cases. In one case the patient had been given huge doses of Warburg's tincture, quinine, and potassium bromide and iodide without any benefit. He had then been given drachm doses of ergot and a marvelous improvement had at once followed. This was three months ago, and the man had had no return of symptoms since. In another case the patient was a lady, aged forty years, who had long been under treatment for migraine, the pain being of a boring character and very difficult to relieve. In this case the value of ergot in the treatment of this affection had been discovered accidentally; it was given to check a menorrhagia, and at the same time it relieved the headaches.

Dr. C. A. HERTER said that in the treatment of these cases he laid greater stress upon the diet and nutrition than he did upon drugs. He employed very few drugs, chiefly aconitine. He was decidedly opposed to the use of the antipyretics. If ergot did relieve these severe periodical headaches, which were often very intractable, it was certainly a great boon.

Dr. Corning said it was important to determine whether the pain was extracranial or intracranial. He referred to the value of compressed air in relieving intracranial pain. External pains, on the other hand, were aggravated by the compressedair treatment.

Dr. Thomson, in reply to a question, said our present knowledge was not definite enough to form any idea as to how ergot acted in these cases. He simply gave it as an empirical remedy. Furthermore, his paper had referred entirely to neuralgias that were definitely periodical. These were usually very severe and entirely different from the ordinary intermittent headaches. He referred to the fact that quinine, even in small doses, when it was combined with ergot, appeared to produce cinchonism much more quickly than when given alone. In only one of the cases reported had there been any antecedent history of malarial infection, and in that case the patient simply had resided in a malarious district. Very probably there had been a malarious element in the other cases, of which the nervous symptoms had been the only manifestations. Dr. Thomson also referred to the fact that intercostal neuralgia was often accompanied by sciatica; also the occurrence of sciatica after pleurisy. The latter combination he had noticed in about twenty cases.

The President referred to the indefinite character of occipital headache. In some recent articles published in Brain some light had been thrown on this subject, the point being to make accurate observations of the distribution of the pain, and then attempt to associate that distribution of the pain field with some organism of the body distant from the pain field, but connected with the same segment of the nervous system that was connected with the nerve in which the pain was felt. Pain in the back of the head must in the majority of cases be associated with irritation in the domain of the occipital nerves, or rather of the upper fourth and fifth cervical segments of the spinal cord, which had extensive connection with other parts of the body through the sympathetic system. Perhaps, if these ob-

servations were further extended, they would explain why in so many cases of gastric or intestinal disturbance the pain was felt not where the irritation occurred, but in the head.

# Reports on the Progress of Medicine.

### PHYSIOLOGICAL CHEMISTRY.

BY ERNEST ELLSWORTH SMITH, PR. D.

The Action of Iron.—In his studies on the assimilation of iron, Bunge, in 1884, concluded that the inorganic salts were not absorbed in appreciable quantities, and hence did not directly give rise to homoglobin formation. When in organic combination, as iron containing nucleo-albumin, etc., iron is absorbed, especially when prevented from being decomposed in alimentation. Bunge suggests that iron salts used therapeutically act in one or both of two ways:

First, by preventing the decomposition of organically combined iron present in the food. This it does by reacting with the sulphide of hydrogen resulting from intestinal putrefactive processes, which, if free to act upon the iron in organic combinations, would cause their destruction and hence prevent its absorption.

Second, that the iron salts administered act as intestinal antiseptics.

Mörner, in a series of experiments on himself, has recently (Ztechr. f. physiol. Chem., xviii, p. 13) studied the influence of large therapeutic doses of iron salts on intestinal putrefaction by estimating the ethereal sulphates of the urine during periods of administration of such doses (ferric chloride) and during parallel and intervening periods without iron when the same conditions of diet, etc., were maintained. The results are entirely negative, the sulphate ratio remaining unchanged despite the large doses of iron administered. Hence it appears that Bunge's second suggestion does not explain the mode of action of iron salts.

Chemical Researches on the Mineral Matter of Bone and Teeth.-Dr. S. Gabriel (Ztschr. f. physiol. Chem., xviii, p. 257) expresses the composition and properties of the ash of bone and teeth by the following general formula: Ca3(PO4)2 + CasHPsO13+2H2O, in which from two to three per cent. of calcium is replaced by magnesium, potassium, and sodium, and from four to six per cent, of phosphoric acid is replaced by carbonic acid, chlorine, and fluorine. The quantity of chlorine amounts to only a few hundredths of one per cent., except in the enamel of the teeth, which contains a relatively larger quantity (0.21 per cent.). Fluorine is a constituent of both bone and teeth. The quantity does not usually exceed 0.05 per cent. of the ash, rarely amounting to 0.1 per cent. In direct contrast to the other solid tissues of the body, bone and teeth contain more sodium than potassium. While the quantities of calcium and phosphoric acid vary only inconsiderably, yet the magnesium and carbonic acid vary inversely with these, so that the sums of the two bases and of the two acids are constant. The distinctive character of the ash of particular bones depends on the variation in the amount of calcium and phosphoric acid replaced, and also on the nature of the replacing radicles. The difference that exists between bone ash and tooth ash is not greater than the difference which has been observed in the ash of different bones. In enamel there is less, and in the body of the tooth relatively more, calcium replaced by magnesium than

cord, which had extensive connection with other parts of the body through the sympathetic system. Perhaps, if these ob-

phate. The relative valence of the acid and basic radicles is as 15:16. Water is present in two combinations—water of crystallization driven off at from 300° to 350° C., and water in chemical combination, driven off at white heat when the substance is mixed with silicic acid.

The Ash of Normal Stools.—Dr. J. Grundzach (Zeit. f. klin. Med., xxiii) believes that previous analyses of the ash of normal faces do not give the actual composition of the inorganic matter present. This is mainly due to the fact that by ignition large amounts of phosphorus and some sulphur are transformed from the organic combinations in which they exist, as in lecithin, nucleo-albumin, and other proteids, into phosphoric and sulphuric acids. Hence the analysis of the ash obtained by ignition yields entirely misleading results regarding the amount of these two acids actually present. By direct determination of SO<sub>3</sub>, P<sub>2</sub>O<sub>5</sub>, and Cl without previous ignition of the substance the following results were obtained, which are here given along with two older analyses for comparison:

Analysis of-	Author.	Fleitmann.	Porter.
C. Harrist I.		0.58	4.33
Sodium chloride Potassium chloride	( Cl 0.844	0.07	4 100
Potassium oxide	12:000	18:49	6.10
Sodium oxide	3:821	0.75	5:07
Calcium oxide	29 · 250	21.36	26 · 46
Magnesium oxide	7:570	10.67	10.54
Iron oxide	2:445	2.09	2:50
Phosphoric acid	$13 \cdot 760 (P_2O_5)$	30.98	36:03
Sulphuric acid	0.653 (SO <sub>3</sub> )	1.13	3-13
Silica	4.460	7:39	30.00

According to the author's views, the alkaline bases not combined with mineral acid, 58:1 per cent. of the total bases according to Fleitmann, 32 0 per cent. according to Porter, and 77.87 per cent. from the present analysis, are combined in fæcal matter with organic acids. It is a function of the epithelia of the large intestine to secrete an alkaline fluid adapted to neutralize and thus convert into soaps the organic acids formed in the small intestine by fermentation of carbohydrates, fats, and perhaps proteids. According to Nencki, Mackfadyen, and Sieber, the contents throughout the small intestine remain acid, and it is not till they have become mixed with the alkaline juices of the large intestine that the neutral and alkaline points are reached and that it is possible for putrefaction to begin. It thus appears from the analysis presented that less of mineral acids exists among the inorganic constituents, and that a very considerable portion of the inorganic bases are in combination with organic acids.

The Chemistry of Muscle, with a Consideration of Rigor Mortis and the Effects of Certain Poisons,—A. Heffter (Arch. f. exp. Pharmak., xxxi) has studied the muscle tissue of cats and frogs. A hundred grammes of fresh muscle were hashed and extracted as described with ninety-six per-cent, alcohol, and aliquot portions of the combined extracts titrated, rosolic acid and phenolphthalein being used as indicators. Calculated to a hundred grammes of tissue, the average acidity with rosolic acid was 28.5 cubic centimetres of one tenth normal sodium hydroxide. as against 60.8 cubic centimetres with phenolphthalein-a difference which was constant, and suggested the presence of a substance acting toward rosolic acid as an alkaline base. On evaporation of the alcohol, extraction with ether, and titration of this ether extract, both indicators gave the same result. The acidity of these various extracts could not be attributed to free phosphoric acid or salts, for analysis revealed only traces of phosphorus, entirely inadequate to explain these results.

The influence of rigor mortis was to increase the acidity of the alcoholic extract only slightly, though constantly. The fresh resting muscle always contained lactic acid—a small por-

tion in a free condition, by far the greater part in the form of salts. Rigor mortis was accompanied with no increase of lactic acid, either free or combined; hence its formation takes place only in the living tissue. Poisons producing tetanus caused a diminution of the amount of lactic acid contained in muscle. By poisoning with carbonic oxide, in consequence of direct injury to the cellular elements by phosphorus poisoning, and by increasing the chemical tonus (action of curare), a diminution of the lactic acid was produced, both of the free and of the combined. The author is in doubt whether in these cases there is an increase in the amount of lactic acid passing from the muscle to the blood, or whether there is an actual diminution in the amount formed in the muscle tissue.

The Composition of the Blood in Health and Disease.-R. von Jaksch (Zeit. f. klin. Med., xxiii) records the results of analyses of blood, both normal and in disease, in which are determined the proteids of the total amount of blood and of the blood-serum, the number of red and of white blood-cells, the amount of hæmoglobin present, and the water and total solid constituents of the blood. The proteids are calculated from the nitrogen as estimated by the Kjeldahl method, the error introduced by the extractives present amounting, even in extreme cases, to only one per cent., as the author shows. Six normal cases were studied, eleven with diseased conditions of the nervous system, four cases of phosphorus and one each of carbonic oxide and nitro-benzol poisoning, ten of diabetes mellitus, nineteen acute cases, mainly of pneumonia and typhus, four cases with diseased livers as the primary affection, six with diseases of the lungs and pleura, thirteen cases of kidney disease, and twenty of various anæmic conditions, making a total of one hundred and four different cases.

In general it was observed that, with a diminution of the cellular elements, particularly the red blood-cells, there was a parallel reduction of proteids contained in the blood. The relation is more constant between the proteid and hæmoglobin; and, in regard to the total solids, there are few exceptions where the number expressing the residue left on drying does not approximately indicate the total of proteids. The relation between the proteids of the entire amount of blood and those of the blood serum is, on the other hand, very variable. This seems to be due not so much to fluctuations in the proteids of the serum as of the amount of blood, although kidney diseases form an exception to this, and show great fluctuation in the proteids of the blood serum. Diminished proteids and an increase in the amount of water present are conditions that exist in all forms of anæmia, yet, as the author shows, exist to a greater or less extent in other diseased conditions, as in typhus, and therefore belong to no particular disease. The author characterizes these conditions as hypalbuminæmia and hydræmia. Observations of these changes in cedema of the lungs were made, and they are interesting as indicating to what extent this condition of the blood serves as a factor in producing it.

It was found that the highest grade of hydræmia might exist without ædema, and, on the other hand, that there might be ædema without an accompanying increase in the water of the blood. And there is no parallelism between an ædematous condition and reduced proteids. In diabetes there is an increase in the total solids of the blood, attributable to the amount of sugar.

Metabolism in Fever.—Dr. Richard May (Zeit. f. Biol., xxx) gives the following conclusions from experiments: 1. The absolute amount of heat produced (caloric production) is increased in fever. 2. This increase depends upon the increased amount of proteids destroyed (fever in hunger). 3. The amount of proteid decomposed in fever can be diminished by the ingestion of carbohydrates. 4. Glycogen decreases in fever

more rapidly than at the normal temperature. 5. The nitrogen carbon ratio in the urine is changed in fever, the urine being richer in carbon. 6. The increase of proteid destruction in fever is chiefly dependent on the increased requirement of the organism for carbohydrates. The degeneration of cells is not essentially related to the increased nitrogen separation in the urine.

Peptone Formation in the Stomach of Infants,-Dr. Siegfried Toch (Archiv für Kinderheilkunde, xvi) has attempted, in a series of observations on the stomach contents, to ascertain whether peptonization occurs as a result of normal digestion in infants, and to what extent such a process is influenced by conditions of disease. At the outset the author falls into error by employing the term peptone in the older meaning and by using a test which does not distinguish between peptones and proteoses. Proteoses are always formed, as is generally known, whenever milk sours, and in some cases perhaps as a result of the action of rennet. Hence in the present observations the author found a positive reaction for "peptone" in every instance, even when only a half-hour had elapsed after taking the milk into the stomach. Further investigation showed him that this could not be justly attributed to pepsin action, since the gastric juice, although containing pepsin, was inactive toward proteids till after the addition of free hydrochloric acid. He therefore is led to believe that the "peptone" (proteose) was formed in every case by the coagulating ferment. His observations are of interest as showing the presence of pepsin in the gastric juice of infants suffering from acute and chronic diseases of the stomach, and led the author to believe that the peptonization of milk so frequently resorted to in disorders of this kind was uncalled for and entirely superfluous.

# Miscellany.

The Status of Acting Medical Officers of the Army.— Dr. John T. Nagle concludes his pampled on The Status of Acting Assistant Surgeons of the United States Army who served in the late Civil War, to which we alluded briefly last week, with the tollowing summary:

The evidence which I have presented is almost entirely derived from official sources, and shows that during the late civil war commanding officers were empowered by the Revised United States Army Regulations of 1861 and 1863 to employ private physicians as medical officers when it was necessary; that these physicians were required to pass an examination before an army medical board, and, if reported favorably by it, they obtained the position of acting assistant or contract surgeon when their services were needed; that before they signed the contract of enlistment to perform the duties of medical officers, agreeably to army regulations, as conditioned in form 18 of the Revised United States Army Regulations of 1861 and 1863, they were sworn into the service by a commissioned officer of the army, in accordance with the form of oath which is prescribed in the 10th article of war which was in force in 1861 and 1863, being the oath of allegiance, service, and obedience, which they were also required to subscribe to, and which was similar to what was required of any officer or soldier before entering the service; that these officers were designated officially as acting assistant surgeons, United States Army, or contract surgeons, and were necessarily assimilated as to their duties, pay, and status to assistant surgeons of the army, with the rank of first lieutenant when serving with troops in the field, but their pay was less

when serving in the United States general or military hospitals; that the Revised United States Army Regulations which authorized their employment were authorized by Congress, formulated by the Secretary of War, and approved by the President; and these regulations were, by the command of the President, published for the information and government of the military service as the sole and standing authority on the matter therein contained, and nothing contrary to the tenor of these regulations shall be enjoined by any commander whatsoever; that they were also discharged by their commanding officers in writing, a copy of which was required to be sent to the surgeon general of the army, stating explicitly the date and cause; that the word "officer" is not defined in the Articles of War of 1861 and 1863 as being limited to commissioned officers; that the orders, passes, and other evidence of superiors show that they were a part of the military establishment and governed by the rules and articles of war and amenable to Army Regulations, and that they were subject to the same control as all other medical officers; that general orders of the War Department recognized them as officers with rank of first lieutenant in the allowance of fuel and quarters; and placed them in the position of commissioned officers; that the act of June 23, 1874 (18 Stats., 244), entitled an Act to Reorganize the Several Staffs of the Army, Sec. 4, reduced the number of contract surgeons by limiting it to seventy-five; that these medical officers were paid from the appropriation for the support of the army suthorized by Congress; that the Treasury Department paid them for services as medical officers; that the United States Supreme Court has decided that, while there was no act of Congress which expressly authorized the appointment of persons, the appropriation by Congress to pay them is a recognition of the validity of their appointment (Wells vs. Nickels, United States Reports, 104, p. 444); that their duties were well defined, being the same duties that were required of commissioned medical officers; that Sec. 4695 of the Revised United States Statutes, in awarding pensions for total disability according to rank of office, gives the acting assistant or contract surgeons the same pension as is granted to a first lieutenant of the military or marine corps; that they were subject to the jurisdiction of courtsmartial, and that Sec. 1342, Art. 64, Revised United States Statutes, specifies that officers and soldiers of any troops shall be subject to be tried by courts martial; that they were required to wear the uniform of an assistant surgeon with the rank of first lieutenant; that they were in charge and had complete military command over the persons (including officers and soldiers of the Veteran Reserve Corps) and property connected with the United States general or military hospitals; that they took their places as officers on military ceremonies and at the mess; that letters submitted from officers of the army, official orders, the Medical and Surgical History of the War of the Rebellion, prepared under the direction of Joseph K. Barnes, surgeon general of the army during the late civil war, corroborates the proof already submitted that medical officers employed in accordance with the Revised United States Army Regulations, known as acting assistant surgeous, United States Army, or contract surgeons, were officers; that the Attorney General of the United States and Solicitor General of the United States gave it as their opinions that acting assistant or contract surgeons were in the military service of the United States on very meager evidence, such as the production of a few orders, and despite the opinion to the contrary of the Judge Advocate General of the Army, whose opinions were at variance with facts and found their way into Winthrop's Digest and were quoted by them; that a Treatise on Military Law, by Lieutenaut Rollin M. Ives, 5th Regiment of Artillery, assistant professor of law, Military Academy, page 61, shows that acting assistant or

contract surgeons were recognized by the United States Court as being in the military service of the United States and entitled to the provisions of Sec. 2166 of the Revised Statutes. This provides that alien soldiers, honorably discharged, are required to reside in the country only one year to become naturalized; that in the same book and on the same page it is stated that they should be considered amenable to military law; that the acting assistant or contract surgeon performed military service under the orders of a superior for a considearble period of time, was paid from the appropriation for the support of the army, was sworn into the service by a commissioned officer, his contract of enlistment being to serve for a period of not less than three months, agreeably to army regulations, was discharged from the service by a commissioned officer, the reasons for which were required to be sent to the surgeon general of the army, is sufficient evidence of enlistment, as set forth by Winthrop's Military Law, vol. i, page 774, entitled Form and Evidence of Enlistment; that medical cadets who ranked as brevet second lieutenants were employed as dressers, etc., under the immediate supervision of the ward physician of a United States general hospital; acting assistant surgeons were generally ward physicians in United States general hospitals, and Section 5, act of Congress, approved August 3, 1861, states that these cadets "shall act as dressers in the general hospitals under the control of the medical officers alone"; that acting assistant surgeons, Unites States Army, were considered competent medical officers by the medical director of the department of Washington; that acting assistant surgeons, United States Army, were considered as medical officers and free from draft by the War Department in the formation of Hancock's Corps (United States Veteran Volunteers); that the medical director of the Department of Arkansas, Pennsylvania, and all other States, recognized acting assistant surgeons as medical officers in official reports; that act ing assistant surgeons, United States Army, were in charge of the river transportation of disabled soldiers and ambulance trains and in charge of the United States general hospitals for the care of contagious diseases, post hospitals, and assigned to regiments in the field whose commanders requested the surgeon general or the medical directors to have medical officers assigned them; that acting assistant surgeons, United States Army, were required to serve as officers of desertion boards, and performed all other duties that were required of medical officers of the army; that the most eminent surgeons and physicians of the country served as acting assistant surgeons; that many who served as acting assistant surgeons, United States Army, are serving as commissioned medical officers in the United States Army, and have served in the United States Volunteers, United States Veteran Volunteers, State Volunteers, United States Colored Troops, and in the Navy; that they were accorded the same obedience from, and the same authority over, the enlisted men as was possessed by the commissioned medical officer; that their authority received the same acknowledgment from superiors, both in the field and in Washington, as was given to the regular or volunteer medical officers, and they were equally held to conform to the rules and articles of war as they were; that such authority and duties could not be exercised by other than officers of rank.

The Eleventh International Medical Congress.—A letter directed to the undersigned by the secretary general of the Eleventh International Medical Congress, dated December 19, 1893, contains the following communications: "American members will pay on the English, French, and Italian railways single fares for double journeys, and will obtain a reduction of twenty per cent. on fares for Italian round-trip tickets. The documents required for their identification will be sent to you in January, and Americans intending to visit the congress will have to apply to you for them. Full particulars concerning the journeys will accompany the documents. Messrs. Thomas Cook & Son, London, Paris, Rome, and Naples, should be applied to for accommodation and for tickets for the excursions at Rome, at Naples, and to Sicily. Such excursions will be arranged at Rome under the guidance of Mr. Forbes, member of several scientific societies and correspondent of the Times-for Naples. three days, including Vesuvius, Pompeii, Capri, Sorrento, Castellamare, Bajae, etc.; for Sicily, ten days from Naples, including Messina, Taormina, Catania, Girgenti, Siracusa, Palermo, and return to Naples. The fares for members of the congress will be considerably reduced, and comprise hotel accomm dations, carriages, guides, boats, etc.-about 70 francs each for the three days and 285 francs for the ten days. Full particulars concerning these excursions will be contained in a leaflet to be added to the instructions and documents for the journey."

From former communications the following are herewith quoted: The member's fee is five dollars, that of his wife or an adult relation two dollars each. Checks or money orders may be sent to Professor L. Pagliani, Rome, Italy. Credentials have been promised in the near future. When they arrive (none were received last year), they may be too late for many who have started or are about to start. The undersigned, who is not informed of the cause of delay, proposes to supply, in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. The North German Lloyd has promised to recognize them. It is suggested, besides, that a passport may increase the traveler's facilities. Only the North German Lloyd (22 Bowling Green) and the Compagnie générale transatlantique (3 Bowling Green) have thought fit to grant any reductions to congressists. The reductions on Italian railways are available from March 1st to April 30th. A. Jacobi, M. D.,

110 West Thirty-fourth Street, New York.

An Army Medical Board will be in session at Washington City, D. C., during April, 1894, for the examination of candidates for appointment to the medical corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application to the Secretary of War before March 15th for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal acquaintance, from at least two reputable persons, as to citizenship, character, and habits. The candidate must be between twenty-two and twenty-eight years of age and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Successful candidates at the coming examination will be given a course of instruction at the next session of the Army Medical School, beginning in November, 1894. Further information regarding the examinations may be obtained by addressing the Surgeon General, United States Army, Washington, D. C.

A Four-years Course at Jefferson Medical College.-At a meeting of the faculty of Jefferson Medical College held on January 8th it was unanimously resolved to institute a compulsory four-years course with the session of 1895-'96. This step, it is announced, was taken in order that the large clinical service of the Jefferson College Hospital (350 cases a day) might be made use of to the fullest extent in carrying out the desire of the faculty to provide advanced medical education of a practical character.

The Society of the Alumni of St. Luke's Hospital held a stated meeting at the hospital on Tuesday evening, the 9th inst. No formal paper was read, but cases were reported by the following members: Dr. Caswell, specific endarteritis with right hemianopsia; Dr. Southworth, two heart cases; Dr. Vaughan, pelvic hæmatocele; Dr. Bailey, ulnar neuritis with tumefaction along the course of the nerve; Dr. Mabbott, cephalæmatomata; Dr. Tiemann, functional albuminuria; Dr. Beyea, splenectomy, also cicatricial stenosis of the pylorus cured by a plastic operation. After the discussion of these cases a collation was served.

Summer Courses in Practical Obstetrics in the Sloane Maternity Hospital of the College of Physicians and Surgeons.-Three courses, each lasting four weeks, will be open to physicians and medical students. Each class is positively limited to six. The three courses will be the same, so the only choice is in regard to the date.

The first course begins June 4th and ends July 2d; the second begins July 2d and ends July 30th; the third begins August 27th and ends September 24th.

Each course offers the following advantages: I. Forty lessons in operative obstetrics (ten each week). Each student in turn will practice upon the phantom all the common and most of the rarer obstetric operations under the instruction of Dr. Tucker (twenty lessons) and his assistants (twenty lessons). These exercises, in connection with the large operative service of the hospital, are of great practical value. II. Attendance at all births in the hospital. About sixty or seventy may be expected in four weeks. Clinical instruction and every facility for observation of births, normal and abnormal, will be given. III. Instruction in the treatment of puerpera and infants. Students in turn will make rounds daily with the house staff and receive clinical instruction. IV. Instruction in abdominal palpation and auscultation and vaginal touch. Examination of gravidæ will be practiced daily by each student in turn. The fee for a course, including the use of the dormitory, is fifty dollars, payable in advance. No partial courses are given. For further information apply to Dr. E. A. Tucker, resident obstetrician.

State Asylums and Lunacy Boards,-The British Medical .Journal for December 23d said editorially:

"We note in the American press a warm dispute between the Lunacy Board of the State of New York and the asylums under its supervision. There are occasionally times in England when the managing committees and the superintendents of asylums feel disposed to resent the interference of the Board of Lunacy in Whitehall. It is impossible, however, for us to conceive the commission even taking the position which they recently assumed in America. There would instantly be a revolt, with a result not difficult to predict. The management of State hospitals for the insane in the United States is essentially different from the county asylums of England. Practically the lunacy board in the former country has come to bear the same authoritative relation to the institution that the County Council, representing the ratepayers, does with us. The committee of management goes to the wall. It is easy to understand that the orders of the latter would be much more likely to be received with respect than those of a board not meeting on the spot, and not in a position to judge of the administrative needs of an asylum. We have not, of course, any right to assume that there has been no need for reform in the expenditure of the New York hospitals for the insane. What seems to us inexplicable is that the power over the commissariat should be transferred from the managers to a central board. The former have issued a protest in which they say 'the commission is a centralization of power, and is putting into three men's hands

boards of managers'; and they add, 'if any manager, any superintendent, or any board of managers has been recreant to their trust, it is proper to publish that fact, but it is neither dignified nor decent by generalization to indulge in wholesale defamation.

"What is called the 'State-care system' came into force in October, 1893. In an article in the Utica Morning Herald, December 4th, a statement is made which, if true, indicates an extraordinary, and indeed intolerable, state of things. 'Under it the State Commission in Lunacy exercises centralized power. No purchases can be made, employees engaged, or repairs effected without its authority. So tightly are the reins of power held that the other day, the supply of oil having given out at the Utica Hospital, and authority to purchase not having been granted, an employee was obliged to carry his State lamp to his home and fill it from his private can!'

"The same paper maintains that the State of New York, in decreeing, as it has done, State care of the insane, did not contemplate 'saving' by the hampering and harassing asylum administration which has now occurred, and proceeds: 'The people will not tolerate any such interpretation of their action or purpose. They are humane and able to provide for such of their fellows as are the most unfortunate of human beings the comforts which the judgment of the trained specialists and intelligent local managers decide to be needful and wise.'

"After reading the articles which this controversy has called forth, it appears to us that under the new system in New York the asylum superintendents in the State are degraded; that the managers can not purchase the smallest item of supply without permission from the commissioners, who revise quantity and prices, and may even suggest where purchases shall be made. It is very evident that estimates may be arbitrarily reduced without regard to the special needs of the asylum, in order to make the taxpayer believe that a great 'saving' has been effected. We confess that, in view of the great abuse of centralization which appears to have been committed by the lunacy board, our sympathies go with the managers who have revolted, in the absence of any proof that they have failed in their duties to the State. If they have failed, let their places be filled by better men. We have no faith in the detailed administration of several asylums by a central board composed, we believe, of only three men."

Cologne Water in the Treatment of Slight Affections of the Air-passages. - At a recent meeting of the Société des sciences médicales de Lyon, reported in La Province médicale for December 16th, M. Gabriel Roux made a preliminary communication on what he termed a very simple and rapid means of cutting short acute inflammation of the upper air-passages at the start. Special reference was had to an affection that is very common in Lyons, formerly described under the name of catarrhal fever, in reality a sort of naso-pharyngo-laryngotracheitis. The remedial measure consists in inhaling very energetically by the nose, but especially by the mouth, several times in the course of the day, cologne water poured upon a handkerchief. The inhalation of the vapors disengaged by the cologne should be deep enough for an intense, disagreeable, and painful, but not persistent, smarting to be felt either in the nasal passages or in the back part of the throat. This inspiration ought to be made either exclusively by the nose or exclusively by the mouth, accordingly as the object is to act upon the symptom of coryza or upon the pharyngo-tracheitis; butand this is to be particularly borne in mind-the jugulatory action is infinitely more decided and certain upon the mucous membrane of the pharynx and larynx than upon that of the nose, more authority than was hitherto intrusted to the several so that inflammation of the two mucous membranes first mentioned will be found to have subsided completely while the coryza still continues. This invariable occurrence warrants a complete separation of the effect produced from that of certain irritant vapors, such as those of ammonia, iodine, etc., on the pituitary membrane. M. Roux gives the history of eleven cases in which the result had been not only excellent, but of truly astonishing suddenness, and he added that it was just this rapidity of action that had induced him to bring the matter before the members of the society, for in itself it was of small importance, but might under certain circumstances be of service. In less than twenty-four hours, indeed, a cold in the head, accompanied by slight fever, chills, prickings in the throat, hoarseness, coryza, and cough, had completely yielded, if the treatment referred to had been used at the outset, after four or five inhalations lasting from two to three minutes each. The form

The New York Academy of Medicine.—The special order for the meeting of Thursday evening, the 18th inst., was a paper entitled Observations on Excessive Intestinal Putrefaction, by Dr. C. A. Herter.

of cologne water used by M. Roux was that of the Hôtel Dieu,

somewhat different from that of the Codex, especially in the

substitution of the essential oil of unripe bitter oranges for

neroli.

At the next meeting of the Section in Laryngology, on Wednesday evening, the 24th inst., Dr. J. E. Weeks will report a case of tracheotomy for syphilitic stenosis of the larynx.

At the next meeting of the Section in Obstetrics and Gynæcology, on Thursday evening, the 25th inst., a paper on Smallcystic Degeneration of the Ovary will be presented by Dr. F. Foerster, and one entitled What are the Indications for a Vaginal Examination? by Dr. E. B. Cragin.

Color-hearing .- In the Gazette hebdomadaire de médecine et de chirurgie for December 16th Mlle. N. Astier gives the following account of her own case: "I must have been seven or eight years old when I began to notice and to signify to others the connection that for me existed between certain colors and certain sounds or letters. In the books of my childhood every letter o was red and every i was blue; these color effects resulted in inducing the other members of the family to perceive the colors which I saw at first, whether by looking at the printed letter or on hearing the corresponding sound. There were only three letters that I saw distinctly: the red o, brilliant and luminous as a fine wild poppy; the i of a dull indigo blue, and the black u. Other vowels and the consonants had no special colors; they borrowed the tint of the nearest colored vowel. Words that contained both o and i appeared violet: this color, which I could not tolerate, brought to my mind certain odious names, among others my own given name, which I could not hear without experiencing the same sort of pain as is produced by hearing a discord. I had a very disagreeable feeling on looking at anything blue or at the letter i, and at the age of eight or nine years I refused to write this letter in the names of those I loved, but I added it to the names of those I disliked. When I read, I saw the color on the book, very vivid on the vowel and radiating all around the word; when I listened to the word, the tint floated before my eyes, without definite form, comparable to a uniform and evanescent phosphene. Figures did not seem to me to be colored, except seven and eight, the former being agreeable and red like o, and the latter disagreeable and blue. Colors were associated also with musical sounds and with noises; the full, rich tones of the organ, those of the violoncello, and those of the voice in the medium register were red, brilliant, and warm; grinding sounds, the harsh sounds of the voice, those of the clarinet,

the quality of the sound, not on the note, and its intensity varied with the instrument. The color sensation evoked by an orchestra depended also upon the quality of the combination of sounds. The impressions caused by seeing color and by hearing sound were of the same nature; the one aroused the other. The scraping of the bow on the finest string of the violin caused a blue spot to appear before my eyes; the sight of this detested blue made me hear sharp sounds or the letter i. I extended these associations to my sentiments of affection; certain persons had a halo of red or blue according as I liked or disliked them. These sensations were extremely intense from the age of nine to that of fourteen. I was then in very bad health and excessively nervous. As my health became re-established I paid a good deal less attention to these phenomena of color-hearing, and when I took a new survey of myself, some years ago, I found that these vowels, read or heard, no longer gave me the sensation of color. One remembrance remains very clear with me; when I hear certain letters or certain sounds, I sometimes think of the colors formerly called up by them, and can occasionally cause a feeble image of them to reappear, but the vision has not been produced spontaneously for a long time now. I never knew any member of my family who was affected with color-hearing."

Proposed Legislation concerning Capital Punishment in Ohio.—We learn that the following bill is to be introduced into the Ohio Legislature during the present session:

"Be it enacted by the General Assembly of the State of Ohio that Sections 7338, 7339, and 7341 of the Revised Statutes of Ohio be amended so as to read as follows:

"Section 7338 amended to read: 1. That all persons sentenced to death by any court having jurisdiction in the State of Ohio shall be held as subjects for experimental research; that such experiments shall be conducted in the interest of science and society, and shall be regulated by approved rules of humane treatment to avoid all unnecessary pain; that in the preparation for such experiments, where pain would be occasioned, anæsthetics shall be administered to the extent of complete insensibility to pain, and during the progress of the experiment narcotics shall be judiciously used to allay any pain, and the condemned person shall not be maltreated in any way; that after the conclusion of such experiments the criminal shall be again anæsthetized and put to death while in a deep sleep and entirely insensible to pain; that the executioner shall be an expert physiologist duly appointed and authorized by the State, and that such appointments to execute and conduct such experiments shall be vested in the Governor, and shall consist of one executioner and five assistant physiologists, with a like number of deputies, who shall hold their office for the term of good behavior, except upon proof of incompetency; and no one so appointed shall be removed without sufficient cause, which shall be left to the discretion of the Governor, and that all appoint. ments to fill vacancies caused by death, resignation, or removal shall be made as prescribed in the foregoing.

2. All executions of the death penalty according to the provisions of this bill shall take place within a building provided for that purpose and so constructed as to safely and comfortably lodge all capital criminals until the completion of the execution; that such criminals shall be in the custody of a warden or deputy warden and board of managers, who shall provide for their safe and comfortable keeping; that the execution of the sentence shall commence on the day fixed by the judge passing the sentence, unless a suspension of execution be ordered by the Supreme Court or two judges thereof.

sounds, the harsh sounds of the voice, those of the clarinet, and those of the violin were blue; the tint always depended on tenced to death, all writs for the execution of the death penalty

shall be directed to the sheriff by the court issuing the same, and the sheriff of the county wherein the prisoner has been convicted and sentenced shall, within the next thirty days thereafter, in as private and secure a manner as is possible to be done, convey the prisoner to the institute provided for capital criminals, where the said prisoner shall be received by the warden and securely kept; and the sheriff shall receive for conducting the prisoner sentenced to death to the institute for capital criminals the same fees and mileage that is [sic] provided by law in other cases, when duly approved by the warden of the institute.

"Section 7341 amended to read: That no one shall be present at experiments and executions except the warden or deputy warden in charge of the prisoner, the executioner, assistants, and deputies, and those who have duly qualified themselves to comprehend the experimental work; that such qualifications shall be determined by a board of examiners, who shall issue a certificate which shall admit the holder to witness the experiments and executions; that at the conclusion of each execution a written report shall be required of the body of physiologists which shall contain a correct account of the result of the experiment and execution, and that such a report shall be made within thirty days from the infliction of death, and recorded in the archives of the institute, and of which a certified copy, together with the warrant, shall be forwarded to the clerk of the county from which the prisoner was sentenced, who shall record the warrant and returns in the record of the case.

"That Section 7338 as amended May 12, 1886, Section 7339 as amended April 29, 1885, Section 7341 as amended March 21, 1887, and Section 7343 as amended May 12, 1886, of the Revised Statutes of Ohio be hereby repealed."

An Early Symptom of Hereditary Syphilis,-The Centralblatt für Chirurgie for December 23d gives a summary of an article by Dr. Carini, of Palermo, published in the Internationale klinische Rundschau, in which the author remarks that children with bereditary syphilis often appear quite healthy at first. The early symptoms hitherto recognized, he says, often do not appear until some weeks after birth, and some of them, like roseola, are so fleeting that an early diagnosis is rendered very difficult. Positive congenital signs are not common. As early a diagnosis as possible may, however, be of the greatest practical importance. Accordingly the author calls attention to a symptom which, although standing in no apparent connection with syphilis, he has observed invariably in his cases namely, the occurrence in the course of a few hours after birth of uncommonly obstinate hiccough, lasting from a week to three weeks. In every case a diagnosis founded on this symptom was subsequently justified. The author believes that this hiccough depends upon a neuropathic diathesis to the development of which syphilis contributes materially. The biccough proves obstinate to all ordinary treatment, but disappears after the mother has taken large doses of potassium iodide and the nursling has been treated with Van Swieten's solution.

A Mode of Compressing the Abdominal Aorta.—In the January number of the Annals of Surgery Professor William Macewen, of Glasgow, thus describes a method that he says he has tested sufficiently to feel warranted in making it public:

As the patient lies on his back on the table, the assistant, facing the patient's feet, stands on the left side of the table in a line with the patient's umbilious. He then places his closed right hand upon the patient's abdomen a little to the left of the middle line, the knuckles of the index finger just touching the upper border of the umbilious, so that the whole shut hand will embrace about three inches of the distal extremity of the aorta above its bifurcation. The assistant then, standing upon his

left foot, his right foot crossing his left and resting upon the toes of the right—an attitude commonly assumed by public speakers—leans upon his right hand and thereby exercises the necessary amount of pressure. With the index finger of the assistant's left hand the weight necessary for the porpose can easily be estimated by the effect produced upon the flow of blood through the common femoral at the brim of the pelvis. Whenever the flow of blood through the femorals is absolutely arrested the abdominal aorta is sufficiently controlled, and no further weight ought to be applied.

The weight exercised can be varied at will by increasing or decreasing the angle which the assistant's body makes with the floor

As the abdominal aorta sometimes bifurcates higher than usual, before the operation is commenced a trial of the effect of the pressure at the part selected ought to be made, testing the result of pressure on both femorals. When both are equally controlled the bifurcation occurs below the point pressed on; when only one is controlled the hand requires to be placed on a more proximal part.

As there is no direct muscular effort required in maintaining the pressure further than the preservation of the equilibrium, the position can be maintained by the assistant without undue strain on his part, and without shifting his hand for at least half an hour, a time amply sufficient for the performance of most operations requiring the control of the circulation through the abdominal aorta.

In order to eliminate the personal equation, the author has usually selected a different person each time he has had occasion to control the abdominal aorta, and, while there were slight differences between the various persons chosen, the object was always efficiently secured. The majority of those who exercised pressure in this way said, at the end of the operation, that they could have further maintained the pressure for a considerable time.

Among the cases in the author's practice in which the abdominal aorta was thus controlled were disarticulations at the hip joint, amputations at the upper third of the femur, large pelvic vascular tumors, intrapelvic hæmorrhage, and traumatic hæmorrhage from the external iliacs; in all the control of the circulation was absolute. In the amputations of the hip none of the patients lost from the proximal side of the cut vessels more than two ounces of blood, and that only from the oozing of the general surface; there was none from the main vessels. In amputations also, after the main vessels were ligatured, the assistant could, by a slight momentary relaxation of the pressure, "show" the position of any bidden or retracted vessel without altering the position of the hand relatively to the aorta. This form of pressure would be equally valuable, the author says, for uterine hæmorrhage.

A priori, he continues, one might fear that pressure might be exerted on some of the coils of the small intestine and thereby produce injury. As far as one can judge, this did not result. Only on two occasions did the patient complain, for a few hours after the operation, of a sensation of pain over the part pressed on, which was only elicited on interrogation. All the others, though specifically asked, said they had no pain.

There is one point to be guarded against. Should the patient vomit or cough violently the pressure would require to be increased, as otherwise the muscles in the abdominal walls are apt, during the strain, to elevate the hand from the aorta. The operation during vomiting might be postponed for a few minutes while local pressure was applied.

The author has applied this method in his practice for over fifteen years, and has found it simple, always ready, easily applied, and efficient.

Mectures and Addresses.

# THE INCH-AND A-HALF INCISION AND WEEK-AND-A-HALF CONFINEMENT IN APPENDICITIS.

A LECTURE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, October 28, 1893,

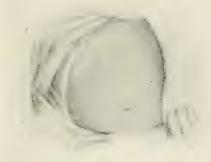

By ROBERT T. MORRIS, A.M., M.D.

In all probability there is not a member of this audience who has not lost one or more friends from appendicitis. That remark applies not only to you, but to every man in the United States, and that means a good many deaths from one disease. These deaths would have been unnecessary if the patients were where they could have had the benefit of the inch-and-a half incision as soon as the first symptoms of appendicitis occurred. Then, again, the subject is unfairly stated in terms of life or death, for I have tried here to lay down the cardinal principle that every hour of progress of an acute attack of appendicitis means increased damage to viscera, and the deduction is clear that patients who run the gantlet without operation are left with many a defect and many an anxiety. The physician who reports the patient as cured after an acute attack has subsided does not intentionally make a fraudulent statement. He is so solicitous for the patient's welfare that he deceives himself. Most of the appendicitis cases that come to us deliberately for operation have been discharged as cured by their physicians. Not long ago two rival physicians were present at the bedside of the patient upon my arrival. Dr. Smith favored immediate removal of the appendix and Dr. Jones was opposed to the idea, stating that he had never lost a case under medical treatment. Dr. Smith, who was rather bluff in manner, said to Dr. Jones: "Oh, yes, I know all about your patients. The ones that died had obscure cases of typhoid fever, or intestinal obstruction, or peritonitis, and the ones that recovered were appendicitis." One reason why the members of the profession are slow in acting according to the principles involved is because no one of artistic temperament enjoys the thought of a great gash in a fair young belly, and that is why I have developed the inch-and-a-half incision and the evanescent scar. The week and a half during which I keep the patient in his room after this operation is less than the average time of confinement with one attack of appendicitis, and then there are no more attacks. The mass of special knowledge in the profession to day is so great that the left hand does not know what the right hand is doing, and post graduate instruction is of great advantage if it succeeds in simply informing men as to what others are about. If unnecessary deaths and disaster from appendicitis are occurring all around us, it does not mean that physicians are neglectful. It means only that men, by conscientious devotion to their patients' best interests, have built up an engrossing practice which, from its very magnitude, obscures the view of a small special operation. As soon as I can establish as standard the inch-and-a-half in-

cision and the week-and-a-half confinement in appendicitis, the general practitioner will have no difficulty in deciding just what to do at the very outset of an attack. Some of the operations that I have done here before the class were upon physicians who came at once for operation in their own cases when they would have hesitated about sending a patient. Bear well in mind the fact that in its nature appendicitis is an infectious inflammation which persists at the focus after medical resources have caused subsidence of any one attack, and do not forget that it causes increased damage to viscera with every hour of progress.

The patient upon whom we are now to operate is a young mother, twenty-five years of age. Shortly after childbirth, a year ago, she was attacked with appendicitis, and has not been quite well since. According to my theory, the efforts of parturition crowded the appendix against the pelvic wall and crushed its adenoid layer. Bacteria entered the injured tissue, which swelled until it choked within the confining tube of muscular and peritoneal coat. If any other part of the bowel had been injured in the same way there would have been plenty of room for the swollen adenoid tube, and it would have protected the patient by its action as a strainer for bacteria, but in the appendix it met with a mechanical obstacle in the narrowness of its muscular and peritoneal sheath.

Let us measure off an inch and a half over the site of our patient's appendix and make the line oblique enough to lie in the trend of the external oblique aponeurosis. An incision three quarters of an inch in length would suffice for this patient, and in a fleshy patient two inches might be necessary; but I am making the incisions here of one length in order to establish a standard. With a little

narrow scalpel I now incise down to the transversalis aponeurosis, and before opening this and the peritonæum a loop of catgut is introduced as a holder for the two latter structures, so that we can find them ready for a neat approximation with sutures after the operation. As the peritonæum is opened you all recognize the broad longitudinal muscular ribbon which is peculiar to the colon. A bit of sodic chloride placed upon the bowel excites reversed peristalsis, and then we know in which direction to follow the colon ribbon, which leads directly to and ends exactly at the appendix. The cæcum and appendix do not come

readily into the opening, so I insert one finger into the abdominal cavity and separate adhesions. This is not to be done through the small incision by any one who is not quite familiar with adhesions. Now you can all see the exposed cocum and the mass of adventitious tissue which bears in its midst the hidden appendix. A very little dissecting exposes the tip of the appendix, and then the whole structure is liberated. It is ligated with a fine strand of eve silk close to the cæcum and the stump is buried with three Lembert sutures. If perforation should occur beneath the ligature, the new adhesions under the Lembert sutures would protect the patient. The only two deaths that I have heard of as occurring after operations "in the interval" of exacerbating appendicitis were caused by perforations of the stump below the ligature, the operators having failed to recognize the fact that perforation was very likely to occur at precisely that point, because the stump tissues, though apparently in quiescent condition, were nevertheless dangerously infected. However, this was a thing which had to be learned in the evolution of the operation before its present ideal technique had been developed. Our next step consists in lifting up on the catgut loop in the wound and accurately uniting the margins of the peritonæum, transversalis fascia and aponeurosis, and internal oblique aponeurosis. Look now at the movements of the external oblique aponeurosis as the patient breathes, and you will readily understand why the surgeon would not unite all structures of the abdominal wall with one tier of sutures, while the muscles were intended by Nature to glide over each other in different lines of traction. The external oblique aponeurosis sutured, an assistant puts the little skin wound upon the stretch with a couple of hooks, so that I can make a beautiful approximation of skin margins with five-day catgut and leave my evanescent scar. These patients do not have hernia after an operation of this sort. Examining the removed specimen, we observe that the larger part of the adenoid and mucosa present the white and cheesy appearance of tuberculous degeneration, while about an inch of the appendix is still whole; but, as the ostrich farmer on the Midway would say, "Bright and lively; going on all the time; no waiting for the performance." If this is tuberculous, as appendices not infrequently are, nothing could illustrate better the farce of waiting for a proper time to operate. The insidious disease would infect the whole peritonæum before the patient was ready to demand operation.

There is no more empty mockery of wisdom than the expression "using judgment" in appendicitis, which perforates, which infects the liver or the lungs, which causes thrombosis of the blood-vessels, at a moment when the patient's pulse and temperature and respiration are all normal and when there is no pain. We shall never have a classification of symptoms in this disease for the guidance of the general practitioner, because the most satanic cases may be cases with practically no characteristic symptoms, and the cases with outrageously definite symptoms may go on to almost perfect recovery. It is enough to know the nature of the disease, and then, acting from a standpoint of principles, the appendix will be removed as a matter of cus-

tom as soon as the first symptoms of appendicitis occur. In this appendix there are no seeds. Seeds in the appendix are mythical for the most part, and I hope that we shall hear less about them in the future, when a more careful examination is made of the seed-like phosphatic or fatty concrements that are so common. I used to find grape seeds and apple seeds and cherry pits in the appendix, but since these have been subjected to exact chemical analysis I frequently make my luncheon of a bottle of koumiss and a couple of pounds of grapes, swallowing every seed, because I have not as yet found anything excepting concrements in the whole collection of seed-like objects from removed appendices.

A member of the class asks why I scarified the peritonæum before burying the stump of the appendix in this patient. That was done in order to excite a local peritonitis for plastic purposes. We need to disturb the peritonæum pretty well in order to get a response. The peritonæum is the surgeon's little friend. It drinks up infected exudates, and it walls in the weak spots. Without the help of the peritonæum we should be unable to do successfully the many abdominal operations which are done with such ease and safety. Peritonitis as a result of surgical operations is something which occurs frequently among the leaves of the older text-books, but it is something with which the surgeon is unfamiliar.

## Original Communications.

#### A CONTRIBUTION TO

THE ARRANGEMENT AND FUNCTIONS OF THE CELLS OF THE CERVICAL SPINAL CORD,

TO WHICH IS APPENDED A NOTE ON CENTRAL CHANGES SECONDARY TO LONG-CONTINUED DISUSE OF AN ENTREMITY.

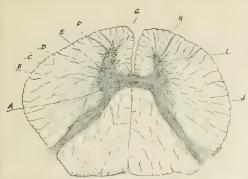

BY JOSEPH COLLINS, M. D.,

VISITING PHYSICIAN TO THE HOSPITAL FOR NERVOUS DISEASES; ATTENDING PHYSICIAN TO ST. MARK'S HOSPITAL; INSTRUCTOR IN NERVOUS AND MENTAL DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

(Concluded from page 45.)

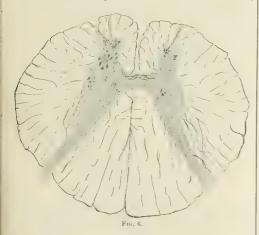

A drawing from the second cervical segment shows (Fig. 5) on the left side of the gray matter the anterior group of cells for the back muscles and the accessorius nucleus to be intact. Stilling's nucleus internally at the junction of the gray commissure and the base of the posterior cornua, and the scattered cells with the beginning of the middle and lateral columns, seem likewise to be normal. At this level on the right side the pathological changes first show themselves. We notice that the anterior nucleus for the back muscles, the accessorius nucleus, and Stilling's nucleus are apparently normal. The middle and lateral cells are, however, almost entirely absent. A few middle and small scattered cells are to be seen at the base of the anterior horn.

As the sections are studied from this point to the third cervical segment, there is very little change from what has just been stated except that the scattered cells on the right side become less numerous. Sections from the third cervical show that the anterior nucleus and the accessorius nu-

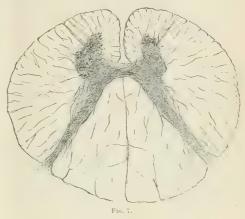

A, lateral cell : B, Stilling's cells ; C, middle cells ; D, scattered cells L, lateral cells; F, accessory; G, anterior group for the back muscles; H, anterior motor cells; I, accessory; J, Stilling's cells.

cleus are intact on the right side, but the scattered cells and a few cells of the middle column that were to be seen in the section above have disappeared (Fig. 6). In some of the sections a few cells corresponding to Stilling's nucleus are to be seen at this level. The anterior group and the lateral cells are entirely absent on this side at this level.

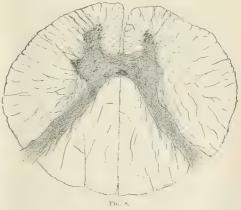

but very distinct and well marked on the left side, as are all the other cell groups. Lower down in the third segment the cells that are to be seen in the ventrad portion of the anterior cornua are not closely differentiated into nuclei (Fig. 7). At this level the nucleus of the phrenic nerve normally shows itself. It is in all probability the presence of the cells from which the phrenic takes its origin that causes the bunched appearance here of the cells in the shrunken cornu.

Sections made from the fourth cervical segment show very marked changes (Fig. 8). The anterior horn of the deficiency in ganglionic cells. It is at the lower level of this segment, it will be remembered, that the prominent lateral groups constituting the upper extremity of this nucleus begin to present themselves in the normal cord, and it is to be seen distinctly at this level on the left side (Fig. 8). On the right side, however, all that can be seen is the nucleus for the back muscles and the accessorius nucleus. The median group, the lateral and the scattered cells are Tall

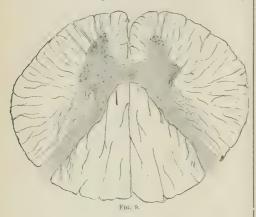

quite absent, excepting here and there in different sections a few scattered cells show themselves. Lower down in this segment the accessorius nucleus is scarcely to be observed. and the nucleus for the back muscles with a few anterior motor cells are all that are to be seen.

Sections made from the fifth cervical segment (Fig. 10) show the difference in the number of cells in the two anterior cornua very strikingly. On the left side the nuclei are

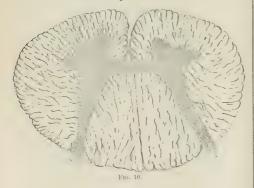

prominent, especially the upper-extremity nucleus. On the right side this nucleus, with the exception of one or two cells situated where the anterior group of this nucleus is right side presents striking shrinking in outline and marked found normally, is quite wanting. The nucleus for the back muscles and the phrenic nucleus are conspicuously present, especially the latter, which at this level presents a perfectly normal appearance.

Passing from the fifth to the sixth cervical segment, we notice (Fig. 11) a marked shrinking in the contour and outline of the anterior horn on the right side. The cells on this side are small in number, and those present are remarkably small in size, their protoplasmic prolongation stunted or very delicate, and their nuclei not very well marked. The accessorius nucleus, which has been intact on this side until the present level is reached, now disap-

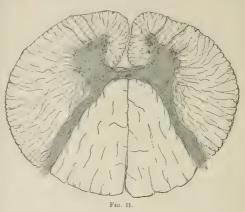

pears. The nucleus for the back muscles still shows prominently.

When the lower level of the sixth cervical segment is reached—that is, at its junction with the seventh (Fig. 12)—there is a very important change to be noticed on the affected side. In the first place, we notice that the cornu

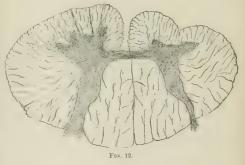

does not present such a shrunken appearance as formerly, although its contour is not yet normal as compared with its fellow. Secondly, and more important, is the presence of a group of cells which heretofore has not been evident. These cells are situated internally near the center of the gray matter; in fact, in the location normally occupied by the internal group of the upper-arm nucleus. The cells

seen are few in number and have a shrunken and stunted appearance. In several of the serial sections they can scarcely be made out, and in none do they present a normal

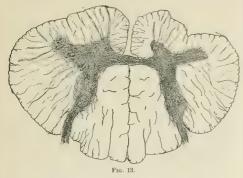

appearance. As we pass into the seventh segment they become less clearly evident. When the seventh segment is reached another important change is to be seen (Fig. 13). On the left or unaffected side the gray matter is normal in outline and the cell arrangement corresponds clearly with what is considered normal. On the right side the outline of the gray matter is shrunken. The cells of the back-muser.

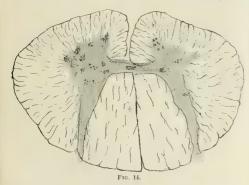

cells nucleus are to be seen very clearly. The group of cells that was seen in the segment above, and which, as was stated, occupied the place of the internal group of the upper-extremity nucleus, has at this level practically disappeared. In a few sections made from the upper part of the seventh segment a cell or two can be seen that belong evidently to this group, but lower down in the segment they are absolutely absent. The important change to be noted at this level is the appearance of a few cells at the lateral periphery externally. When the cells are first detected in this location they are small and insignificant looking and few in number. As we descend, however, they assume a more important bearing, and when the eighth segment is reached we see (Fig. 14) this group very prominently brought into view. From its location we are led to

believe that it is the anterior group of the upper-extremity nucleus. It continues into the first dorsal segment. The cells of this group present less of the shrunken, atrophied

appearance than any of the other cells that have been found in the lateral gray matter on this side. Just at the level of the eighth cervical their protoplasmic prolongations are really quite well marked. As regards the other cells at this level, what has been said in reference to the appearance of the seventh cervical segment applies as well to this. It is noteworthy that the cornua at the level of the first dorsal segment are nearly quite alike in outline.

Before closing what is to be said regarding the changes found in this cord it is well to recall the more important

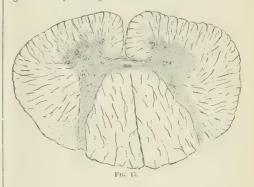

data that have been indicated. To recapitulate, then, briefly, the changes found in the cells of the cervical portion of this cord were as follows:

- 1. The group of cells situated toward the apex of the anterior cornua internally, and which is generally believed to give origin to the nerves that innervate the muscles of the back was intact on both sides.
- 2. The accessorius nucleus on both sides was apparently normal.
- 3. Stilling's cells presented themselves with sufficient frequency to be considered normal on both sides.
- 4. The medial group of ganglionic cells ordinarily observed at the upper portion of the fourth cervical segment and extending to the sixth was present on the left side.

On the right the posterior portion was well represented throughout its entire extent. The anterior portion of the group did not always show so clearly.

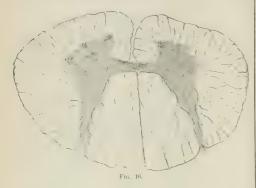

5. The most striking change was to be seen in the groups of cells known as the upper-extremity nucleus, ordinarily called the lateral groups. This nucleus of cells, which was very well marked on the left side and presenting in three portions, was nearly absent on the right. At the level of the lower margin of the sixth and in the seventh segments a few cells were found in the position ordinarily occupied by the internal group, while at the level of the eighth and first dorsal a comparatively large number of cells was found in the position occupied by the anterior group of the upper-extremity nucleus.

It remains for us to consider the pathological findings in this case in relation to the movements of the upper extremity that the patient was capable of. It will be remembered that the only movement that the patient had in the right extremity was slight flexion and extension of the fin-

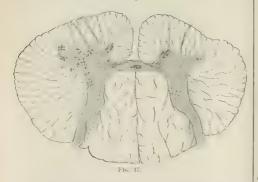

gers; that pronation and supination of the hand, flexion and extension and rotation of the forearm, were impossible. On the other hand, he was a strong, vigorous man, working at ordinary labor that could be accomplished with one hand, and this suffices to show, without further emphasis, that the muscles of the neck, back, abdomen, legs, and the respiratory muscles were of good nutrition and properly innervated. It is therefore in entire keeping with this statement that the nuclei for the back muscles, the neck muscles, the diaphragm, and the muscles of respiration were found on the right side as well as on the left. The fact that a column of cells extending uninterruptedly in the same relative position throughout the cervical portion of the cord, and that the muscles which it is said to innervate were normal, tends strongly to corroborate the opinion that the group of cells in question, situated in the interior interno-lateral portion of the anterior cornu, is the nucleus of origin for the nerves supplying the muscles of the back, and is therefore properly termed the "nucleus for the back muscles." When we consider that the muscles supplied by the brachial plexus were almost entirely paralyzed on the right side, it is quite in keeping that the ganglionic cells furnishing the origin of the brachial plexus on this side should be extremely atrophied or absent. In

this case they were mostly absent, except here and there a scattered cell found in some of the serial sections. That the patient was capable of making some slight movements of flexion and extension of the fingers pointed to the fact that there were remaining some cells in the cord from which the nerves of the brachial plexus arose that were still functionating to a limited extent. It will be remembered that certain cells were found in the seventh and eighth cervical and in the first dorsal. It will likewise be remembered that these cells were found in relatively two different positions—one internally and one at the periphery. It is quite probable that one set of these cells caused the flexion of the fingers and the other the exten-

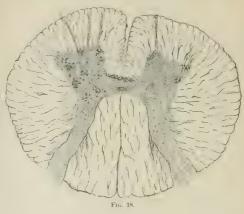

sion. It is desirable to know which did which. In order to determine this it is necessary to consider somewhat in detail the anatomy of the brachial plexus and the deep origin of its roots according to the best investigations. Before doing this, I desire to call attention to the corroborative evidence that the pathological findings in this case give to the statement which is considered a fact—that the lateral group of cells in the gray matter are concerned in giving origin to the nerves entering into the formation of the brachial plexus; that this nucleus begins in the lower part of the fourth cervical segment and extends into the

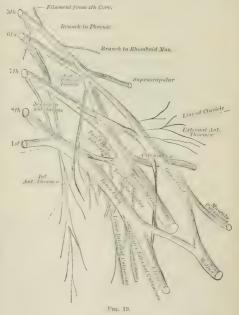

first dorsal segment; and that the name of upper-extremity nucleus is so apropos that, for the sake of clearness, it should be adopted.

A reference to the accompanying drawing of the brachial plexus, which was designed by Walsh (Fig. 15) and based on a personal dissection of the brachial plexus in three

hundred and fifty subjects, demonstrates that the greater part of the outer strand of the median nerve is formed from the anterior branch of the fifth and sixth uniting with the superior branch of the seventh. The inner strand

of the median is formed largely from the eighth, with small branches from the seventh cervical and first dorsal, while the musculo-spiral, the nerve that innervates the extensors of the hand and forearm, arises from the fifth, sixth, seventh, and eighth, the sixth supplying the least and the seventh the most. The ulnar, it will be seen, has its origin from the eighth cervical and the first dorsal.

A diagram made by Forgue and Lannengrace and modified by Thorburn, Ferrier, and Yeo, represents the segments of the cord wherein are situated the nuclei of ganglionic cells for the different muscles supplied by the brachial plexus.

It will be seen that the flexors of the fingers and the muscles on the anterior surface of the hand in general are supplied by the nerves originating in the last cervical and first dorsal segments. Possibly a very small amount of nerve supply may come from the seventh segment to supply the flexor carpi ulnaris. The nuclei of ganglionic cells in the seventh segment, and less so in the eighth, supply the extensor muscles of the back of the forearm, and therefore the extensors of the fingers and hand. It will be recalled that in the case described the cells of the upper-extremity nucleus that were present were at the seventh cervical segment, and to a slight extent above and below this level were arranged internally. Now, knowing as we do that the extensor muscles of the fingers have their origin at this level, it is justifiable to conclude that these cells found in this place were responsible for the ability to extend the fingers that this patient was possessed of. On the other hand, it will be seen by reference to the drawing (Fig. 14) that sections between the last cervical and first dorsal show a group of cells laterally; and again, the nuclei situated at these levels we suppose to be concerned in supplying the muscles that cause flexion of the fingers. Their presence in this case, and likewise the ability to flex the fingers having persisted, would point to the fact that our ideas concerning the functions of this group have not been amiss.

Thorburn, from an extremely careful clinical study, has reached conclusions concerning the location of muscle nuclei in the cervical cord that differ somewhat from those obtained from simple anatomical investigation, such as those of Herrington. Thorburn gives his results as follows:

Supraspinatus
Teres minor Fourth cervical segment.
Biceps )
Brachialis anticus
Deltoid
Supinator longus
Supinator brevis
Subscapularis
Pronators
Teres major
Latissimus dorsi } Sixth cervical segment.
Pectoralis major
Triceps
Serratus magnus
Extensors of wrist Seventh cervical segment.
Flexors of wrist Eighth cervical segment.
Interossei
Intrinsic muscles, First dorsal.

Comparing these statements of Thorburn with the results heretofore set forth, it will be seen that our statements coincide very nearly with the results obtained clinically.

In our case there was a complete absence of cells of the upper-extremity nucleus until the lower portion of the sixth cervical segment was reached. A glance at the table, taken from Thorburn, shows that the sixth cervical segment innervates some of the chest muscles, such as the pectoralis major and serratus magnus, as well as the subscapularis, pronators, teres major, latissimus dorsi, and triceps. If this be a fact, these chest muscles must be supplied by the group of cells found internally at the level of the sixth cervical segment (see Fig. 12), for the other muscles just enumerated, with the exception of the latissimus dorsi, were paralyzed in our case. The important muscles supplied by nerves arising from the fifth cervical segment—

such as the biceps, brachialis anticus, deltoid, and supinator longus and brevis—were entirely paralyzed. Correspondingly there was a complete absence of cells of the upper-extremity nucleus at this level. The same may be said of the fourth segment.

There have been a number of cases—some of chronic anterior poliomyelitis, some of intra-uterine amputation and congenital absence of a limb, and others of atrophy of certain individual muscles—carefully reported which, when the findings are analyzed and compared, tend to localize (rather indefinitely, some of them) the function of the cells of the

upper-extremity nucleus in the different segments of the cord.

Monakow has reported a case in which there had been long-standing paralysis of the extensors of the hand and fingers. Examination of the spinal cord showed atrophy of the internal group of cells of the upper-extremity nucleus in the lower part of the sixth and seventh cervical segments.

In a case reported by Prevost and David, in which there had been atrophy of the thenar eminence, a lesion was found in the eighth cervical segment and very slightly above this level, involving principally the internal group of the upper-extremity nucleus, although the anterior group was affected to a slight extent.

Edinger has reported a case of congenital absence of the left hand and the larger portion of the left forearm, only a stump the size of a child's fist being attached to a normal elbow. The patient had always been a strong, hearty man, and died at the age of fifty-two years from valvular disease of the heart. The cord in the upper cervical portion was quite alike in its two halves. On section, the atrophied state of the gray matter could be seen with the naked eye in the sixth and seventh cervical segments

on the left side. A more careful examination showed the left anterior horn to be atrophied from the lower level of the fourth segment to the first dorsal, the greatest atrophy being apparent between the exit of the sixth and seventh nerves. The cells of the upper-extremity nucleus in the affected area showed a remarkable falling off in number. The other cell groups were also affected, insomuch as their cells were atrophied and appeared like Deiters's cells. The ulnar, median, and radial nerves in Edinger's case were greatly atrophied, and the author gives it

Frg. 21. Right cerebral hemisphere

as his opinion that the atrophied portion of the cord contains the nuclei of origin for these nerves. He does not commit himself regarding the functions of individual groups.

Hayem has reported a case of atrophy of the cervical cord secondary to an amputation of the right forearm. The patient died seven years after the operation, and the atrophied area in the cord was principally in the seventh and eighth cervical segments and the first dorsal. It is not possible to say from the report just what groups of cells were atrophied, but the anterior and median groups of the upper extremity nucleus suffered most severely. Other cases have been reported by Kahler and Pick, Ross, Troisier, Serres, Tiedemann, Gurlt, and others, but the conclusions to be drawn from them do not differ materially from those stated.

Ferrier has published some very interesting inferences drawn from experiments made by himself and Yeo on monkeys. Although his conclusions can not be accurately applied, so far as the construction of the brachial plexus in man is concerned, still they are quite in keeping with the knowledge that has been obtained in man by other methods. Ferrier found that, in stimulating the anterior root fibers entering the formation of the brachial plexus with the faradaic current, the following were his results:

Fourth Cervical.—Deltoid, supraspinatus and infraspinatus, teres minor, triceps, brachialis anticus, supinator longus, extensors of wrist and fingers, diaphragm.

· Fifth Cervical.—Deltoid (clavicular portion), biceps, brachialis anticus, serratus magnus, supinator longus, extensors of wrist and fingers.

Sixth Cervical.—Latissimus dorsi, pectoralis major, serratus magnus, pronator (flexor of wrist), triceps.

Seventh Cervical.—Teres major, latissimus dorsi, subscapularis, pectoralis major, flexors of wrist and fingers (median), triceps.

Eighth Cervical.—Long flexors, ulnar flexors of wrist, intrinsic muscles of hand, extensors of wrist, phalanges, long head of triceps.

First Dorsal.-Intrinsic muscles of hand.

In fact, all the evidence that we may collect seems to corroborate the statements that we have already made concerning the relative position of nuclei in the upper-extremity group for the different muscles of the upper extremity.

It remains for us to say a word concerning the generalizations that may be made from our present knowledge of cell grouping in the cervical cord.

We have already stated that the most constant cell group in the spinal cord is the one situated anteriorly, near the apex of the anterior cornu internally, and that its function is to supply the muscles of the back-i.e., extensor muscles. Again, it has been stated that the group of cells found in the seventh cervical segment were internally in the gray matter, and that they were concerned in giving the nerve supply to the muscles that caused extension of the fingers. Considering, then, the functions of these groups to be as stated, I would suggest that the nearer a ganglionic cell group is to the median line the more apt it is to represent the origin of extensor muscles. The more distant it is, the more apt is it to represent the flexor muscles. I am aware that this statement concerning the relative position of the cell groups indicating whether they are for the flexors or the extensors is at variance with the statements of some previous writers (Spitzka); but it seems to me that the conclusions drawn are justifiable. Therefore, in cases of injury where the extensor muscles show the greatest amount of paralysis, it may be concluded that the injury

Fto. 20.-Left cerebral hemisphere.

to the cord is more deeply situated than if the flexors were the most paralyzed, and *vice versa*. The same may be said of disease of the cord.

The cells of the lateral or upper extremity nucleus that were found on the right side in our case were, as has been

said, few in number, and those found were small, with very weak and delicately-appearing protoplasmic processes, and less well marked angular or polygonal appearance than the cells of corresponding groups of the other side of the cord. This is due to the functional inactivity of the parts which they supplied, for, although there was slight ability to flex and extend the fingers, the extremity practically was motionless, and therefore the cells functionated very slightly. It has recently been shown that ganglionic cells, when they remain inactive for a great length of time, soon take on a similar appearance to cells that have been greatly overworked, and this appearance corresponds very closely to what has been stated as the appearance of the cells in the diseased portion of this cord.

It has been stated many times, and evidence has been brought forward to support such statements, that the cortical areas, in which are situated the functions of motion, often atrophy as the result of long-continued disuse of an extremity (Edinger's case). This specimen gives corroborative evidence in that line. It is unnecessary for me to say that the motorial areas on the external surface of the brain are situated mainly on either side of the fissure of Rolandothat is, in the ascending frontal and ascending parietal convolutions. It is known also that the area for the arm and wrist are situated in the ascending frontal convolution about midway between the longitudinal fissure and the horizontal limb of the fissure of Sylvius. The shoulder center is just above this, but in both convolutions—the ascending frontal and ascending parietal-while the center for the fingers and thumb is just below it. Now, if there is a manifestation of atrophy in the external surface of the brain in this specimen, it should involve these three centers on the left sidethe side opposite the one in which the disease showed itself in the spinal cord.

That as accurate information might be obtained as possible, the brain was carefully suspended in Müller's fluid for a few days until its consistence became such that the pia could be carefully removed; the brain was then photographed. Examination of the accompanying photographs (Figs. 17 and 18) will show that the convolutions on either side of the fissure of Rolando of the left hemisphere are considerably narrower than those of the right, except near the longitudinal fissure. In order that the size of the convolutions might be compared readily, the fissure of Rolando on each side was mathematically divided into tenths, and then the diameter of the convolutions measured at each of these points.

On the right side the measurements, numbered from above downward, were as follows:

Right ascending frontal.	Level.	Right ascending parietal.
Millimetres. 16 12 12 12 11 11 11 6	I. II. III. IV. V. VI. VII. VIII.	Millimetris. 7 14 12 14 7 14 15
12 9	IX. X.	9

On the left hemisphere the measurements gave-

Left ascending frontal.	Level.	Left ascending parietal
Millimetres.	-	Millimetres.
17	I,	10
20	II.	20
18	III.	17
13	IV.	13
11	V.	8
13	VI.	8
9	VII.	7
10	VIII.	19
14	IX.	18
8	X.	11

The depth of the fissure of Rolando at ten different levels was obtained in two ways, and the results obtained were averaged. The average is here given. In the first way a slender bit of wood with a blunt end was passed down to the bottom of the fissure of Rolando and then measured at the point where it came on a level with the cortex cerebri, great care being taken that it did not enter the substance of the brain. By the second method the fissure was carefully increased in size by spreading the convolutions, and then a piece of tin foil was forced to the bottom of the fissure and the measurements were then taken. They indicated on each side as follows:

Left fissure of Rolando.	Level.	Right fissure of Rolando
Millimetres.		Millimetres.
14	I,	10
15	II.	13
10	III.	12
11	IV.	14
10	V.	11
8	VI.	10
9	VII.	10
11	VIII.	12
7	IX.	6
10	Χ.	4

Too much stress should not be laid on the significance of these measurements. The fact that the convolutions of the brain vary very extensively in size and somewhat so in conformation is well known. The same may be said for the fissuration of the brain. Still it may be said that great pains were taken to get these measurements accurately on both sides; and as they show a shrinkage in the size of the convolutions and the depth of the fissnre of Rolando of the left side, particularly in the upper-extremity area, it is not amiss to refer to it.

A reference to the tables shows that on the left side at the fifth, sixth, and seventh levels the parietal convolution was very narrow as compared with the parietal convolution on the opposite side. The left ascending frontal convolution is also smaller at these levels than its fellow of the opposite side of the brain. The fissure of Rolando likewise is shallower at these and lower levels.

After the measurements were taken the motorial areas were sectioned at the ten levels along the fissure of Rolando indicated above, and two pieces removed from each section, which, after proper hardening, were stained, the one with carminate of sodium, the other with hæmatoxylin. The thickness of the cortex cerebri was about the same in sections taken from either side of the brain, and this thickness varied, as it does normally, the sections made from the apices of the

convolutions presenting the deepest cortex. In the sections stained by the Weigert method it can not be said that there were any findings that could be considered as abnormal. The layer of connective tissue beneath the pia was thin and normal in appearance, as were the medullated fibers beneath this layer. The network of fibers in the layer of the small pyramids presented as close and well-formed arrangement on the left side as on the right. And the same can be said of the fiber network below the external stripe of Baillarger. In fact, with the hæmatoxylin stain it was impossible for a skillful microscopist to pick out which specimen came from the right motorial area and which from the left.

Sections stained by the carminate-of-sodium stain did, on the other hand, show a change which is worthy of attention. The cells of the third layer, or the giant pyramidal cells of Betz, seen in specimens taken from the left motorial area, were not so conspicuous as those seen in sections taken from the right side. Although the writer does not care to state that they were much lessened in number in any given section, it was noteworthy that in many of the sections, particularly those taken from the fourth, fifth, and sixth levels of the left motorial area, these cells were smaller in size and not so closely arranged in clusters as in sections made from the motorial area on the other side. Their protoplasmic prolongations seemed finer and less sturdy and the nuclei took on a deeper hue than the nuclei of the cells from the right motorial area.

It is believed by many physiologists that the layer of pyramidal cells, or, as it is often called, the ganglion-cell layer, is the location for the essential motor cells. This is the view that is strongly advocated by Ferris. If this view can be accepted—and it can at least as an extremely probable hypothesis—it is a very significant fact that in our case the cells of the motorial area governing the paralyzed arm should be found in a condition resembling atrophy.

In conclusion, I would advance the following statements, based upon the foregoing investigation:

- The great majority of the motor cells of the cervical spinal cord have a certain definite arrangement.
- 2. Some of these cells are arranged in columns which extend through many segments of the cord.
- Certain definite functions can be assigned to certain cell groups and succession of groups making up a cell column.
- 4. The cell groups giving origin to the brachial plexus are three in number, and they extend from the upper portion of the fourth cervical segment to the lower portion of the first dorsal. The cells of the upper portion of this area supply the muscles of the shoulder and upper arm. The cells of the lower portion supply the forearm and hand. The nucleus for the flexors is externally and at a lower level than that of the extensors.
- The cells giving origin to nerves that innervate extensor muscles are situated nearer the median line than those supplying flexor muscles.
- The group of cells innervating the back muscles is situated ventrad and internally in the anterior cornua.
  - 7. The motorial function of any part or extremity is in

direct relation to the number and health of the ganglionic cells in that segment of the cord from which the nerve going to said part originates.

8. In cases of long-standing disuse and disability of an extremity there occurs in the opposite side of the brain in the location corresponding to the cortical area for said extremity an atrophy both in the size and constituents of that area.

### NOTES ON TWO HUNDRED AND FIFTY CASES OF EPILEPSY.

BY R. K. MACALESTER, M. D. (ZURICH).

ÆTIOLOGY AND SYMPTOMS.

This report is based upon the histories of two hundred and fifty cases of epilepsy, treated in Professor C. L. Dana's clinic at the New York Post-graduate Medical School and in his private practice, and presents briefly the following notes concerning this familiar affection. These cases represent, therefore, all classes of society, being gathered from the two aforesaid sources. The main object in view is to compare the ages of patients, especially at the time of onset, with those recorded by some other writers.

Age. Divided into decades, the ages of patients applying for treatment range as follows: First decade, forty-five; second, seventy-six; third, sixty; fourth, forty-five; above forty years, twenty-four. The second decade, it will be observed, shows much the largest proportion of cases, and the third about a fifth less. The first and fourth decades show an equal number of cases, while after the latter period there are relatively few.

Nativity .- The nativity of patients: Born in the United States, a hundred and sixty-four; Germany, twenty-six; Ireland, seventeen; England and Scotland, eight; Italy, seven; Canada, six; Austria-Hungary, five; Scandinavia, four; Russia, four; other countries, nine.

Of a hundred and one patients born in the United States, the nativity of the parents has been recorded in our histories as follows: Born in the United States, eightyseven; Germany, forty five; Ireland, thirty-one; England and Scotland, twenty-one; Russia, eight; Canada, three; Switzerland, three; France, two; Italy, two.

CAUSES .- It is usually customary to divide the causes of epilepsy into two classes-the predisposing and the exciting; but, as several of the causative factors may belong to both of these divisions-as, for instance, infantile convulsions, chorea, excesses, etc.—I do not think it advisable to make this distinction in the following:

Heredity .- Investigations as to the neuropathic family taint have been made in a hundred and sixty-nine of our histories, and it has been noted in fifty-two cases, or thirty and four fifths per cent.

The observations of some other writers may serve as a comparison: Echeverria, twenty-eight per cent.; Gowers, thirty-six per cent.; Putzel, twenty-three per cent.; Reynolds, thirty-one per cent.

An hereditary neuropathic influence on paternal or maternal side, direct or otherwise, has been recorded as follows: On paternal side (in father), epilepsy in seven, and other neurotic and mental affections in six cases. On maternal side (in mother), epilepsy in two, and other neurotic and mental affections in fourteen cases. In other antecedents (father's and mother's family), epilepsy in sixteen, and other neurotic and mental diseases in twelve cases. A further manifestation of a neuropathic predisposition is the existence of some neurotic disease in the brothers and sisters of those affected. For instance, in fourteen of our cases the brothers or sisters were affected with epileptic attacks, while in ten others they suffered from some other neurotic disease, such as infantile convulsions, chorea, migraine, etc., and insanity.

Among other predisposing and exciting causes the following may be enumerated in the order of their frequency:

Excesses .- In forty-four cases: Alcoholism (with or without the inordinate use of tobacco) in parents, ten: in patients themselves, fourteen cases; excessive smoking alone, in two cases; sexual excesses, in nine cases; physical and mental strain (overwork, worry, anxiety, excitement, etc.), in nine cases.

Infantile Convulsions.—In twenty-seven cases.

Traumatism, with symptoms of genuine epilepsy following and persisting, in twenty-four cases-viz., injuries to head and body in twenty-three cases, and to peripheral nerves in one case.

Phthisis .- In parents, in seventeen; in patients themselves, in three cases.

Acute Febrile Diseases (measles, scarlet fever, typhoid fever, pneumonia, etc.).—In seventeen cases.

Infantile Hemiplegia.—In sixteen cases.

Fright and Shock .- In eleven cases.

Birth (long, hard labor, instruments used, etc.).—In ten

Gastro-intestinal Affections.-In four cases.

Exposure to High Temperature (sun or furnace).- In four cases.

Chorea. - In three cases.

Syphilis. - Congenital in one; acquired in two cases.

Pregnancy.-In two, and abortion in one case.

Menopause .- In three cases.

Rhachitis.-In two cases,

Vaccination Poisoning.—In one case.

Bad Food (?). - In one case.

The following have also been frequently recorded as preceding or associated with the onset of the diseaseviz., menstruation, marriage, masturbation, and mental depression.

Thus we find a large number of ætiological factors noted in our records-viz., two hundred and forty five. But, notwithstanding this, no cause, either predisposing or exciting, could be ascertained in nearly half of the cases. The large number of causes above enumerated is explained

by the fact that frequently two or more of them have been noted in connection with the same case, as, for instance, heredity as predisposing and injury as exciting cause, or heredity and infantile convulsions as predisposing and injury as exciting cause.

It is not my intention to discuss the causes of epilepsy in detail. Only, en passant, I should like to emphasize what a prominent place excesses occupy among the ætiological data noted in our records.

Sex .- Our records show a hundred and thirty-eight males to be affected to a hundred and twelve females-a marked preponderance of the male sex-which is in concord with the data given in statistics by Althaus, Celsus, Eulenburg (seventy-three males, fifty-nine females), Joseph Frank, Hamilton, Lauret, Putzel (seventy-five males, fiftynine females), Revnolds (forty-nine males, thirty nine females), Sandros, and Webber (a hundred and two males, sixty females). The opposite ground has been taken by Beaumas, Esquirol, Gowers (who in 1,450 cases found the proportion of females to males to be about 6 to 5), and Moreau, who, by the same methods, prove the preponderance of the female sex, while Eichhorst, Hammond (two hundred and ninety-eight males, two hundred and seventyfour females), Nothnagel, Starr, and others consider the sexes to be nearly equally affected.

Age at Onset.—Noted in a hundred and ninety-seven cases, the onset occurred as follows: During first five years, in fifty-one cases, twenty-six per cent.; from five to ten years, in twenty-six cases, thirteen and a quarter per cent.—together, thirty-nine and a quarter per cent.; from ten to twenty years, in sixty-five cases, thirty-three per cent.; from twenty to forty years, in forty-eight cases, twenty-four and a quarter per cent.; above forty years, in seven cases, three and a half per cent.

In regard to the fact, unanimously stated by the various authors, that about three quarters of the cases of epilepsy develop in the first twenty years of life, our records thoroughly agree, for we find seventy-two and a quarter per cent. during this period.

According to other writers, the decade from ten to twenty years is the period that marks the onset of by far the largest proportion of cases—viz., nearly a half or even more of the total number.

Thus, Gowers records forty-six per cent., Hamilton seventy-one out of a hundred and ninety-three cases, Hammond three hundred and twenty-nine out of four hundred and seventy-two cases, Reynolds a hundred and six out of a hundred and fifty-two cases. Webber is of the same opinion, while Nothnagel advocates the period of from seven to seventeen years. Our records show thirty-three per cent. as originating in the second, but thirty-nine per cent. in the first decade of life—the highest number in any one decade—which is quite at variance with the aforesaid writers, but in accordance with Starr, who gives, in a collection of a hundred and sixty-seven cases, fifty-one as beginning in the first and forty-six in the second decade.

It will be further observed that during the first five years of life a remarkably high percentage of cases developed—twenty-six per cent.—exactly double as many as in the following five years, which is a much higher ratio than that given by others. For instance, Gowers's proportion for these two periods is 241 to 181; Starr's, 29 to 22 cases.

In other respects our records only confirm the results of other statistics that go to prove that above the age of twenty fewer and fewer cases develop, and that after forty years the onset of the disease is of comparatively rare occurrence.

Symptomatology.—Aura.—Aura has been recorded in only forty-two cases, although it has evidently been investigated in the majority of our histories. It is described as some general or special sensory disturbance, such as epigastric or abdominal aura, or unpleasant dizzy sensations, or dreamy, "starry" feeling, or flashes of light, sounds in the ears, sensations of breezes blowing, etc. Among the peculiar and rarer auræ were desire to go to stool, the fit coming on just as the patient starts, disagreeable odors, hemianopsia,

Character of Attacks.—Noted in two hundred and twelve histories: Haut mal has been noted in eighty seven cases; mixed form in sixty-nine; petit mal in thirty-four; haut mal with Jacksonian epilepsy in fourteen; rotatory epilepsy in two; psychical epilepsy in six.

Frequency of Attacks.—Noted in a hundred and sixty-seven histories: One or two attacks monthly in forty-four cases; irregular and in groups in forty-one; one to more attacks daily in twenty-nine; one to two attacks weekly in twenty-eight; one to two attacks yearly in twenty-five.

Time of Attacks.—Noted in a hundred and twenty-six histories: Diurnal and nocturnal in fifty-nine cases; diurnal attacks only in forty-seven; nocturnal in twenty.

Mental Condition.—In thirty-six cases mental disturbances have been recorded, as weak or weakening or melancholic mental conditions, defective or poor memory, depression, etc. In ten cases, irritable, bad temper, or quarrelsome. In five cases, idiotic.

Stigmata.—In twenty-nine cases stigmata have been noted and described as: Defective development of head and body; badly shaped, large, or lobeless ears; projecting fore-head; unequal pupils; high, arched palate; crowded, uneven, badly-developed teeth; curious-shaped or deformed head; asymmetry of face or head; prematurely closed or open fontanelles, etc.

Hemiplegia.—Infantile hemiplegia has already been mentioned among the "causes" as occurring in sixteen cases. This condition coexists with genuine, general epileptic attacks.

Transient hemiplegia, supervening upon epileptic attacks (the so-called post-epileptic hemiplegia), has been observed in six cases.

To be continued.)

A Registry for Trained Nurses has been opened at the Presbyterian Hospital, corner of Madison Avenue and Seventieth Street. A prompt response is assured to those making application for nurses. There is no fee; only necessary messenger or telegraphic service will be charged for. The hospital has a telephone, which will be found a ready means of communication from any part of the city.

#### THE EYE TREATMENT OF EPILEPTICS.

A CRITICAL REVIEW OF

CERTAIN FACTORS THAT MAY LEAD TO CONVULSIVE SEIZURES,
AND THE TREATMENT OF EPILEPSY WITHOUT DRIGS.

#### BY AMBROSE L. RANNEY, A. M., M. D.

(Continued from page 83.)

Case VII .- Mr. S., aged sixteen years, student.

Family History.—Many cases of phthisis have occurred in maternal ancestry. All of paternal ancestry are extremely nervous and excitable. The father is intemperate, extremely irascible, and often difficult to control; at times he has been considered partly insane. He has very marked eye defects.

A brother of the patient was an epileptic, partially idiotic, and an inmate of a school for the feeble-minded until he died.

History of the Case.—First examination made April 6, 1889. Patient has always suffered from an extremely weak stomach, and at intervals from peculiar attacks, supposed to be fainting attacks.

Eye Defects.—Under atropine  $1.00~\mathrm{D}$ , of hypermetropia was found.

While testing his eye muscles this patient complained of great distress in his stomach and was immediately seized with an epileptic attack in the office. He had had several such attacks (at varying intervals) while at a preparatory school.

At the third visit he showed the following tests: Adduction, 33°; abduction, 3°; sursumduction—right, 1°; left, 2°; esophoria, 5° to 10°; left hyperphoria, 1° to 2°. In accommodation he showed an exophoria of 4° and + 1·00 s. glasses were ordered for reading. Esophoria prisms (1° each) were given for constant wear.

At subsequent interviews it was found to be difficult to complete the muscular tests on account of distress in his head and stomach. He showed, however, an esophoria that fluctuated from 8° to 15°; adduction, 38°; abduction, 2°; sursunduction—right, 3°; left, 3°. Esophoria prisms (2° over each eye) were continued.

Treatment and Results.—A graduated tenotomy was performed during November, 1889, on each internal rectus, and his prisms were removed. Six months after the last tenotomy the patient showed: Adduction, 25°; abduction, 6°; sursumduction—right, 2°; left, 2°; no hyperphoria; esophoria, 0° to 2°.

In an interview with his mother about six months ago she stated that her son had not had a single epileptic attack to her knowledge since the operations on his eyes over two years and a half ago.

Case VIII.—Mr. O., aged twenty-eight years, single, minister of the gospel. Referred to me by Dr. M. A. H. Hart, of Milton, N. H., on October 28, 1892.

Family History. -No epilepsy or allied diseases among his ancestry.

History of the Case.—The first paroxysm occurred while the patient was a student at the Andover Seminary after a hard evening's work at study. Altogether four typical epileptic attacks have occurred in addition to one or two of petit mal. Three of these attacks have occurred during the past twelve months. The last attack occurred while reading in a moving passenger car. Patient has taken bromides regularly during the past year, and was sent to me by his physician for the purpose of determining whether any reflex causes existed for the attacks. The patient appears to be in good physical health and wears the following glasses, given to him by Dr. Lewis Dixon, of Boston: O. D. -2.50 s.  $\bigcirc -0.50$  c., axis  $180^\circ$ ; O. S. +0.50 s.  $\bigcirc +1.00$  c., axis  $180^\circ$ ; O. S. +0.50 s.  $\bigcirc +1.00$  c., axis  $180^\circ$ ; O. So courred until these glasses were given for constant wear.

Eye Defects .- At the first examination the patient was found

to have a crossed diplopia of 15°, with an apparent right hyperphoria of 2°. His abduction was 17°. Under atropine the following refractive condition was found: O. D., V.  $_{2.5}^{+0.5}$ , made  $_{2.6}^{2.6}$  by -2.50 s.  $_{\odot}$  -0.50 c., axis 180°; O. S., V.  $_{4.0}^{2.0}$ , - made  $_{5.0}^{2.0}$  by +0.50 s.  $_{\odot}$  +0.50 c., axis 115°.

With this correction, the crossed diplopia was unconquerable when a red glass was placed before either eye. Without the red glass the following muscular tests were elicited: Adduction, 8°; abduction, 17°; sursumduction—right, 6°; left, 4°; right hyperphoria, 2°; exophoria, 16°.

Treatment and Results.—With such extreme heterophoria, it was deemed wise to perform a free graduated tenotomy at once upon the right external rectus. After the operation patient disclosed: Exophoria, 6°; right hyperphoria, 3°; abduction, 12°.

Subsequently a tenotomy for a right hyperphoria was performed, as the patient then disclosed 5° of right hyperphoria, with a sursumduction, right, of 8°; left, 1°+. Results after this operation: Right hyperphoria, 1°; exophoria, 5·5°; adduction, 28°; abduction, 14°.

It was decided later to operate on the left external rectus. Results after this operation: Right hyperphoria, 0.5°; exophoria, 3°; adduction, 27°; abduction, 9°; sursumduction—right, 5°; left, 4°. In accommodation, esophoria, 4°, with full refractive correction.

The patient now shows no diplopia, either vertical or lateral, with or without a red glass. Within the subsequent week the patient showed no hyperphoria; exophoria, 1°; adduction, 27°; abduction, 10°; sursumduction—right, 5°; lett, 5°.

It was a great surprise to me and at the same time a source of much gratification that in so short a time (about one month) an approach to ocular equilibrium in this patient had apparently been attained. It was of course possible and perhaps probable that some latent heterophoria still existed, which might require further investigation and correction; but I deemed it wise at this time to instruct the patient to desist as far as possible from reading and study for a few months and to live an out-of-door life.

I recognized the fact that up to the time when glasses were first given him by Dr. Dixon, of Boston this patient had practically been a monocular being, using his left eye chiefly and discarding or suppressing the images in his myopic eye. As soon as his myopia was corrected in the right eye the patient unconsciously was forced to use the two eyes simultaneously, and his extreme heterophoria became an active factor in producing reflex nervous troubles. I was hopeful that after orthophoria was nearly established this patient might tolerate a full correction of his refraction; but I suggested to the patient at the last interview that it might be well for him to discard his distance glasses in case epileptic seizures should occur. I tried to impress upon him the gravity of his malady, the necessity of careful observation of the frequency of his attacks, the length of time required for the complete solution of such cases as his own, and, above all, the importance of abstaining from bromides during the investigation of his ocular problems.

It was a great surprise to me, therefore, when I received a letter from this patient in November, 1893, stating that he had abandoned the eye treatment and returned to bromides.

Case IX.—Miss S., aged thirteen years. Referred to me by Dr. S. B. Casey, of Brooklyn, May 28, 1888.

Family History.—Mother is very nervous. One brother, aged fifteen years, is very defective mentally. One paternal aunt died of phthisis.

History of the Case.—Patient developed epilepsy at the age of ten. Prior to that age she had noticed visual disturbances of a peculiar kind. As she expresses it, "everything seemed to

move downward." Had been an unusually bright child up to the time of the epileptic attacks.

For some months the attacks steadily increased in frequency until they averaged one a week. She was then put under bromides in various combinations.

In spite of the bromides and the extraction of five teeth, she continued to have two attacks a month, the two always following each other.

In April, 1888, at my suggestion, the experiment of discontinuing bromides for two weeks prior to the beginning of eye treatment was contemplated, but within twenty-four hours a condition of continuous epilepsy developed, which seemed to threaten the life of the patient. It was found necessary at once to resume the bromides in large doses. A letter from the physician, dated May 5, 1888, says: "I must say freely that I am unable to promise more in this case than to modify the frequency and severity of the attacks."

Eye Defects.—On May 25, 1888, the patient showed: Right hyperphoria, 0.75°; esophoria, 4° to 10°; adduction, 15°; abduction, 3°; sursumduction—right, 2°+; left, 2°—. Under atropine: O. D., V.  $\frac{200}{200}$ , made  $\frac{20}{20}$ — by + 1.50 s.  $\bigcirc$  +0.75 c., axis 95°; O. S., V.  $\frac{200}{100}$ , made  $\frac{20}{20}$ — by + 1.75 s.  $\bigcirc$  0.75 c., axis 115°. Subsequently a very large amount of latent muscular trouble was discovered.

Treatment and Results.—A full correction for her refraction was ordered, atropine being instilled into the eyes whenever ciliary spasm manifested itself. Within two weeks a graduated tenotomy was performed upon both internal recti and all bromides were discontinued. The eye tests showed no hyperphoria; esophoria, 0° to 3°; adduction, 30°; abduction, 9°—; sursumduction—right, 2°+; left, 2°+. No attacks for six days followed the cessation of bromides. All headaches stopped at once, and a marked drowsiness that accompanied the bromide treatment has entirely disappeared.

July 22, 1888.—The following report was made: "No attacks have occurred for the past three weeks; bromides have been withdrawn for six weeks."

The eye tests remain unchanged from last note.

September 4, 1888.—The spherical strength of the distance glass was decreased  $+1^{\circ}00$ , the cylinder remaining the same, the reason for this change being a persistent tendency to ciliary spasm that exhibited itself at intervals.

October 4, 1888.—Patient shows: Adduction, 28°; abduction, 11°; exophoria, 0° to 2°. She has had only two seizures in about five weeks, one of them preceding menstruation. No bromides have been administered during the past four months. Her expression has undergone a very remarkable change for the better and her physical condition is very much improved.

A report on September 3, 1889, shows that no severe attack has occurred since July 29, 1889. Most of the slight seizures that have occurred have appeared during or just prior to menstruation. She has passed over four weeks without any seizure during this period. Her eye tests on this date showed no hyperphoria; exophoria, 0° to 1°; adduction, 27°; abduction, 8°; sursumduction—right, 2°; left, 2°.

December 23, 1889.—Patient reports that "she has had only five light attacks during the past ten weeks, in some of which she did not lose consciousness."

A letter, dated June 12, 1890, from a brother of the patient says: "It has occurred to me that you may have considered that ingratitude has been shown by a failure on my part to indicate how much my dear sister has improved under your advice and direction since the first visit made at your office. My sister has done well since her last visit to you. She is attacked monthly with one or two slight seizures, each decreasing in

intensity until, according to her own statement, she merely felt the coming on and then it went away."

This patient moved away from close proximity to New York some four years ago; hence I have not had an opportunity of testing her eyes for that period.

I have endeavored to get a report of her condition, but thus far have not been able to obtain her present address.

Case X.—Mr. F., aged forty years, married, teacher. Referred to me October 22, 1890.

Family History.—Mother living, aged seventy years. Father died at sixty-three years of age, probably of scrofula. One brother has had nervous prostration. No phthisis or nervous tendencies, so far as known, in any of the ancestry.

History of the Case.—Six or seven years ago the patient began to have momentary lapses of consciousness with pallor, followed by sweating and confusion of mind. For the past two years these have happened every five or six weeks. A number are liable to occur at these periods in succession. These attacks are usually attended with nausea; would last about one minute, and would be accompanied by a peculiar dullness of perception and memory that would slowly disappear. The patient would be unfitted for work for from thirty-six to forty-eight hours, and several attacks would occur each day while he was so afflicted. Three weeks before I saw him, while driving, he suddenly became pale, stopped talking, gave a cry, and had a typical epileptic seizure. He was unconscious for half an hour.

Patient has had internal hæmorrhoids to an exaggerated degree with some prolapse of the rectum.

This patient had never taken any of the bromide salts.

Eye Defects.—Without atropine, patient tolerated + 0.50 s. for distance. Under atropine, vision of each eye §§, made §§ by + 1.50 s. He also disclosed esophoria, 6°; left hyperphoria, 0.75°; adduction, 22°; abduction, 4°; sursunduction—right, 2°+; left, 2°—. With a red glass placed over either eye the patient shoued homonymous diplopia. After wearing 3° esophoria prism for a couple of days, patient showed no hyperphoria; esophoria, 6°; adduction, 30°; abduction, 0°.

Treatment and Results.—On October 27, 1890, a graduated tenotomy was performed upon the right internal rectus. Result: Apparent esophoris, 1°; abduction, 6°.

An investigation of the esophoria by prisms during the ensuing week disclosed a high degree of latent esophoria (8°) with a decrease in abduction (2°).

A graduated tenotomy was then performed upon the left internal rectus. Result: Apparent esophoria, 0° to 4°; abduction, 6°+.

One week later (November 10, 1890) patient was called home. He showed: Esophoria, 1°+; no hyperphoria; adduction, 34°; abduction, 6°; sursumduction—right, 2°—; left, 2°—.

He was ordered + 1.00 s. glasses for reading and for constant wear as soon as they caused no annoyance; and to return later for subsequent investigation of the eye conditions. I suspected at the time that the latent esophoria was still but partially relieved.

During the next year the patient was seen for about one week daily, during which time his ocular muscles were exercised by overcoming prisms. He disclosed (as I suspected that he would) some  $6^{\circ}$  of latent esophoria, and for part of the year he wore constantly  $+1.00 \text{ s.} \bigcirc 1.5$  prism, base out, over each eye. During this year he had one slight convulsive attack and five attacks of nausea.

During October, 1891, graduated tenotomies were performed on both interni for the relief of the esophoria which he disclosed. He returned home three days after the last tenotomy, showing: Esophoria, 1°; abduction, 8°; adduction, 38°. The esophoria prisms were removed from his distance glasses.

January 19, 1892.—Patient reports one attack of nausea lasting about a week. The spells of nausea during this week he states "were not intense or long continued, but came on several times during the day and night, but there were no convulsive seizures."

A letter dated June 19, 1892, reports a week of nausea during the month of April, less severe than the preceding one. He says: "I think I have gained considerably, and am told that I am looking better than usual at this time of year."

November 15, 1893.—Patient visited the office for the first time in two years. He showed: Esophoria, 0.5°; no hyperphoria; adduction, 27°; abduction, 4°.

The patient has had no epileptic seizure for over two years and only one attack of nausea during 1893. He came to New York for the purpose of being operated on for hamorrhoids. The fact that his abduction continues to be low leads me to think that there is still some esophoria remaining in this case. This I propose to investigate, if possible, before his return home. He appears to be in the best of health.

Case XI.—Mr. B., aged twenty-two years, single, taxidermist, sent to me March 27, 1891.

Family History.—Both parents are living. Father has had frequent epileptic seizures since his fourteenth year. Maternal relatives have severe headaches. No phthisical tendencies. No other cases of epilepsy in ancestry are recalled.

History of the Case.—Patient began to have epilepsy during infancy, while teething. He had no more seizures until his eighth year, when he had several fits. He then went until his fourteenth year without another attack. Since then he has had them quite regularly. He has taken bromides for some years, but none for the past six months.

During the past six months patient has had over one hundred severe attacks. He averages at least one a week and often goes only five days without an attack. He is generally totally unconscious during a fit; bites his tongue, but has no aura. He has received several minor injuries by falling. He averages at least twenty-five attacks of petit mal a day, in which he loses consciousness, but does not fall.

Patient has a good appetite, sleeps well, and has very little headache. Urine normal.

Eye Defects.—Patient showed the following eye tests: Hypermetropia, under atropine,  $+0.75 \, \mathrm{s}$ ; adduction,  $27^\circ$ ; abduction,  $3^\circ +$ ; sursumduction—right,  $2^\circ +$ ; left,  $2^\circ +$ ; manifest esophoria,  $5^\circ$ ; no hyperphoria. Later he disclosed considerable latent esophoria.

Treatment and Results.—Full correction for his hypermetropia was given for constant wear. Graduated tenotomies were performed upon both interni within a week. Results after second operation: Esophoria, 1°; abduction, 9°; left hyperphoria, 0.25°. Up to April 6th the attendant of this patient reports that he has had no attacks of grand mal and his attacks of petit mal are much less severe and less frequent. The patient was obliged to return home, and was instructed to report again for observation after the lapse of eight or ten weeks.

On May 1, 1891, a report from the patient states: "I have had three marked attacks since I saw you—two on April 9th and one on April 22d. I do not think I have had as many spasms as I had previous to my coming to see you. The neighbors tell me that I look greatly improved."

May 13, 1891.—Patient was found dead on the banks of a small stream with a wound in his forehead, caused by a small stone on which he had apparently fallen. His hypermetropic glasses (ordered for constant wear) were found in his pocket.

Case XII.—Mrs. G., aged thirty years, married, three children, referred to me by Dr. E. W. Hedges, of Plainfield, N. J.

Family History.—Unknown. No hereditary predisposition to epilepsy as far as discovered.

History of the Case.—A letter from Dr. Hedges (January 26, 1893) says: "I have advised Mr. G. to take his wife to you in hopes that you can cure her of epilepsy. She has had attacks for three or four years, following closely upon the birth of her last child. Thinking that a lacerated cervix, with angry, everted lips, might have something to do with it, I sewed up the rent; but she is no better, and if anything worse. I have been so much pleased with the results of your treatment in Mr. B.'s case that it gives me great pleasure to send you another epileptic with the hope that you may be equally successful with her."

Subsequent conversations with her husband elicited the fact that his wife had been kept thoroughly under the influence of bromides, and that continuous epileptic seizures were liable to occur for many hours, at intervals, in spite of the drug. These paroxysms of epilepsy would often last one or two days. The patient was at this date in the South, and the reports from her were extremely unfavorable.

March 1, 1893, this patient was brought to my office for examination.

Eye Defects.—Vision was apparently normal; but, under atropine, the following refractive errors were discovered: O. D., V.  $\frac{2}{5}$ , —, made  $\frac{2}{5}$ , by + 1.00  $\bigcirc$  + 0.50 c., axis 90°; O. S., V.  $\frac{2}{7}$ , made  $\frac{2}{5}$ , by + 1.25 s.  $\bigcirc$  + 0.50 c., axis 90°. Examination of her muscles disclosed: Adduction, 27°; abduction, 5°+; sursumduction—right, 2°-; left, 2°-; esophoria, 2°; no hyperphoria.

Within two days, latent esophoria of 7° disclosed itself, patient meanwhile wearing a full correction for her refraction. Her abduction ran down to 2°, and her adduction increased to 38°

Within a week graduated tenotomies were performed upon both internal recti. The effect of these operations was to increase the abduction to  $8^{\circ}+$  and to decrease the manifest esophoria to  $1^{\circ}$ . It was found the patient would not accept her full correction for hypermetropia and her glass was decreased + 0.50 s.

The physical condition of this patient was a very bad one. Her face was covered with an extreme bromide eruption; ber mental powers were very sluggish; she was extremely weak and required an attendant; and was frequently attacked with paroxysms of uncontrollable sobbing and nervous excitement.

Qetober 30, 1893.—Since the last note this patient has had an attack of searlet fever and her two children have been similarly attacked. She has taken no bromides since March 12, 1893. She has entirely regained her normal mental condition, has increased twenty-eight pounds in weight since her last visit, and has had no epileptic seizure for over two months.

During August she was somewhat irregular in wearing her glasses, and she had twenty-five hysterical seizures, some of which seemed epileptiform in type. Since that time she has worn her glasses constantly and no hysterical attacks have occurred.

November 18, 1893.—Patient reports that she has had no hysterical or epileptic seizure for three months. She shows: Vision  $\frac{2}{10}$  in each eye with her glasses; adduction, 27°; abduction, 7°; sursumduction—right, 2°; left, 2°; esophoria, 1°.

Her husband, who accompanied her, stated that he considered her as well, and that they were soon to move to the West on account of some new business connections.

A later report (January, 1894) states that she remains absolutely free from hysterical or epileptic seizures.

CASE XIII.—Mrs. W., aged thirty years, married, three children. Referred to me April 8, 1893, by Professor A. A. Smith, of New York city.

Family History.—Mother had considerable headache; father is strong and healthy. No hereditary tendency toward nervous diseases or phthisis.

History of the Case.—Urine normal. After the birth of her last child this patient began to have epileptic seizures while residing in high altitudes in the West. She was placed under bromides, but the seizures continued at varying intervals and tended to increase rather than diminish.

She came to New York for medicinal treatment, and was referred to me later to see if any light could be thown on the exciting causes of her attacks.

While no very satisfactory record of the frequency of her attacks could be obtained, the reports made by her husband during the first week that she was under my personal observation show that several marked epileptic seizures occurred within the first week. Her husband also stated that he was afraid, on account of the frequency of her epileptic seizures, to have her take her meals in the public dining-room of a hotel, as he never felt sure when they would not occur.

Generally the seizures had occurred immediately after awakening from a night's sleep.

Eye Defects.—On the first visit to my office, April 8, 1893, this patient showed emmetropia, having \(^2\)2 y sion in each eye under homatropine and tolerating no plus glass; adduction, 23°; abduction, 6°; sursumduction—right, 2°—; left, 2°—; no esophoria; no hyperphoria.

Although the patient showed for two days no manifest muscular defect, her low abduction led me to suspect a latent esophoria.

The patient was therefore given a 1° esophoria prism for twenty-four hours. The following day she disclosed esophoria, 1.5°; abduction, 4°+. Within ten days (by the judicious wearing of prisms) she showed over a 5° prism: Esophoria, 7°; no hyperphoria; adduction, 39°; abduction, 0°; and homonymous diplopia whenever a red glass was placed before either eye without the prism.

I was myself somewhat surprised to find, at the beginning of my investigation of this patient's eyes, an apparent orthophoria with an absolute emmetropia. The serious malady with which she was afflicted and its persistency (in spite of medication) led me naturally to hope for a marked refractive error, and probably also a manifest heterophoria.

It took fully ten days of careful observation in this case before I felt that I was justified in performing a graduated tenotomy, or even in extending to the patient any basis of hope for improvement from the eye treatment.

Treatment and Results.—On April 19, 1893, I performed a graduated tenotomy upon the right internal rectus. Result after operation: Esophoria, 1°; no hyperphoria; abductiou, 10°—. Three days later this patient showed esophoria, 0·5°; no hyperphoria; adduction, 33°; abduction, 8°; sursumduction—right, 2°; left, 2°.

Since this operation no epileptic seizures have occurred. The patient has been seen at intervals during the past nine months and very little change in her eye tests has been observed. At her last visit to me, in January, 1894, she stated that she was, in her opinion, "absolutely well."

CASE XIV.—Mr. S., aged nineteen years, single, telegraph operator. Referred to me, March 2, 1893, by Dr. J. B. Hulett, of Middletown, N. Y.

Family History.—Father died of Bright's disease. Mother has some headache. No hereditary tendencies to nervous diseases so far as known.

History of the Case.—Urine normal. Up to the tenth year of age the patient was perfectly well. At that time he had what was supposed to be a fainting spell.

At twelve years of age the patient had his first severe epileptic seizure. Another followed in a few months, and he was put under bromides. For nearly seven years he took the bromides constantly, but continued to have epileptic seizures at varying intervals. Occasionally he would go three months without a seizure, but more often he would have one every two weeks.

For the past three months he has taken no bromides and the frequency of his attacks has not been materially altered by their withdrawal. Two weeks before coming to me he had two severe attacks in one day.

Eye Defects.—This patient had  $\frac{2}{10}$  vision in each eye under homatropine and tolerated no plus glass. He showed on the first examination: Left hyperphoria, 0.25°; esophoria, 0.25°; adduction, 25°; abduction, 6°; sursumduction—right, 2°; left, 2°.

On account of his low abduction, latent esophoria was susected.

Under the influence of a 1° esophoria prism, which was worn by the patient for twenty minutes, he showed: Esophoria, 3°5°; no hyperphoria; abduction, 5°. Within a few days he wore with comfort a 5° esophoria prism and showed: Esophoria, 7°; adduction, 37°; abduction, 2°; no hyperphoria.

Treatment and Results.—On March 17, 1893, a graduated tenotomy was performed on the right internal rectus. After the operation the patient showed: No esophoria; abduction, 9°. Two days later the patient showed: Esophoria, 0.5°; adduction, 37°; abduction, 8°. The patient went home and resumed his vocation, with instructions to return after the lapse of a few weeks.

April 17, 1893.—Patient visited my office and reported that he has had no attacks during the past five weeks. He shows: Esophoria, 0.5°; no hyperphoria; adduction, 38°; abduction, 6°+; sursumduction—right, 2°; left, 2°.

On April 25, 1893, this patient was seized with an epileptic attack. During the fit he overturned a lamp, which set fire to his clothing and burned him so that his life was for a time despaired of. On December 2, 1893, this patient reported at my office for further examination of his eye defects. He states that he passed over six months without any epileptic seizure. During October, 1893, a slight seizure appeared, but since then he has been apparently well and does not even have any of his old apprehensions of an approaching epileptic fit. He discloses no hyperphoria; esophoria, 1°; adduction, 30°; abduction, 7°.

On January 9, 1894, the patient reported that he had passed three months with no attacks, and only one epileptic seizure had occurred in over nine months.

Case XV.—Mr. P., aged twenty-six years, single, merchant. Family History.—Maternal relatives are all more or less nervous and most of them have eye defects.

Father has very marked difference in refraction of the two eyes with an approach to vertical strabismus.

One brother has had a few attacks of epilepsy. One sister was a chronic invalid for many years, until her eye defects were rectified by me.

History of the Case.—This patient's first attack occurred in 183, and he has had them at irregular intervals ever since. They occur always at night. He usually bites his tongue during the attack. This is often the only way that he knows he has had an attack, as he finds a little blood on the pillow. During the past year he has had six severe epileptic seizures. He has taken bromides during the past few years without any apparent influence upon his attacks.

He has been troubled all his life with the most obstinate

form of chronic constipation, for which he has taken cathartics regularly every night at the advice of different physicians. This finally produced piles so badly that several operations were necessary for their removal. He has always noticed that he is more liable to have an attack when he is troubled the most with constipation.

He has consulted several prominent neurologists, all of whom have told him that his attacks were genuine epilepsy and in curable except by bromides. His mother finally became discouraged with the negative results of the bromide treatment and brought him to me for diagnosis and treatment on September 7, 1892.

Eye Defects.—At the first visit this patient showed the following eye tests: Vision under homatropine \$\frac{3}{6}\$ in each eye; slightly improved by + 0.50 c., axis 90°; no hyperphoria; esophoria, 2°; adduction, 23°; abduction, 5°; sursumduction—right, 2°+; left, 2°+.

Within a week, while wearing a 5° esophoria prism, he showed: Esophoria, 7°; no abduction; adduction, 35°. Unconquerable homonymous diplopia when the prisms were removed. Later he disclosed a very high degree of latent esophoria.

Treatment and Results.—Three graduated tenotomies were performed, two on the right and one on the left internal rectus. The latent esophoria was developed by the judicious use of prisms before each operation. The last operation was performed on November 18, 1892.

Since that time the patient has been seen at frequent intervals and his eye muscles carefully tested; but he shows a condition of practical orthophoria. His tests at his last visit, September 14, 1893 were: No esophoria; no hyperphoria; adduction,  $45^{\circ}$ ; abduction,  $8^{\circ}$ —; sursumduction—right,  $2^{\circ}$ +; left,  $2^{\circ}$ +.

The patient had an epileptic seizure the day after the first examination of his eyes, and another light attack in January, 1893. Since then he has had no epileptic attack of any kind and reports that he has a movement of the bowels every day regularly without cathartics; has abandoned all drugs for that purpose; has gained very markedly in weight, and considers himself perfectly well. He has taken no bromide salts since his first visit to my office.

On December 1, 1893, this patient had an epileptic seizure that was quite severe, followed by vomiting. I am informed that he had been exercising violently each day for some months and had lately been taking cod-liver oil without my knowledge. That seemed to cause a gastric derangement.

Case XVI.—Mr. H., aged eighteen years, referred to me by Dr. C. E. Stephens, of Syracuse, N. Y., on March 23, 1893.

Family History.—No hereditary tendencies to nervous diseases, so far as is known.

History of the Case.—Patient has been afflicted with attacks of petit mal for a number of years, and for the past few years has had numerous attacks of grand mal. Bromides were tried, but had no marked influence upon the attacks.

When he came to me for examination he was averaging one attack of grand mal a month, and from two to fifteen at tacks of petit mal a day.

These attacks of *petit mal* were described by him as "whirling attacks," in which objects appeared to dance before his eyes, whether open or shut, in various fantastic forms.

A number of these seizures were observed in the office and found to be genuine attacks of petit mal. His conversation would be abruptly stopped; his head would turn slightly to the left with some twitching of the mouth; he would matter a few incoherent words, rub his eyes, and in a minute or two return to his former condition of mind. He is very sluggish mentally,

but perfectly rational. The whole aspect of the patient was that of a person who was somewhat defective mentally. His movements were slow and he had a peculiar drawling articulation

Eye Defects.—The eye conditions of this patient were particularly difficult to solve. It seemed almost impossible to get any satisfactory tests either for refraction or heterophoria. Patient had marked divergent strabismus and before atropine was used his vision was only  $\frac{2}{4} = 0$ —and could not be improved. Under full atropine his vision was made  $\frac{2}{3} = 0$ —by  $+2.50\,\mathrm{s}$ , in the right eye and  $+1.00\,\mathrm{s}$ , in the left eye. No accurate muscular tests could be obtained, as the patient could not be made to see two images even with a red glass. He was very slow in speech and had several "whirling" attacks during the tests, An ophthalmoscopic examination showed no abnormal condition of the retina.

Treatment and Results.—A full correction was given for his hypermetropia and atropine used until he would tolerate it. Free graduated tenotomies were performed upon both external recti. After the operations patient showed very little lateral jump on exclusion, but apparently some vertical jump for right hyperphoria. He was sent home with instructions to keep up the use of atropine and report weekly.

October 25, 1893.—Up to this date the patient has had but two attacks of grand mal since March last, having gone at one time four mouths without an attack. The patient seems to think that his attacks of petit mal or "whirling attacks" have been much less frequent.

It is still impossible to obtain any accurate muscular tests, as the patient does not seem to have binocular vision. He uses either eye at will, but seems unable to see with both eyes at once. His face indicates a right hyperphoria and he has a slight vertical jump on exclusion. A 2° right hyperphoria prism was combined with his distance glasses and the patient sent home for a few months.

The inability to get any muscular tests makes this case a very difficult one and leaves me in doubt as to what his future treatment will be.

(To be concluded.)

## AMPUTATIONS PROTHETICALLY CONSIDERED.\*

BY GEORGE E. MARKS, A. M.

INTERCOURSE with a considerable number of surgeons—those who reside in the centers of prothetical industry as well as those who inhabit more remote parts—discloses a lamentable absence of knowledge on the subject of amputations when viewed in the light of prothesis.

In consequence of a want of familiarity with this aspect of the subject, we artificial-limb makers have frequently brought to our presence stumps that are good, bad, and indifferent; stumps that could have been better; stumps that reflect credit, discredit, and no credit on the surgeons who performed the amputations, or on those who attended to them after the amputations were performed; stumps that can readily be inserted into artificial limbs with the assurance that no trouble will follow and that the possessors will live in the sublime consolation of having realized the removal of their disabilities for all practical purposes; stumps that might have been better and would have been beyond

<sup>\*</sup> Read before the Section in Military Medicine and Surgery of the First Pan-American Medical Congress.

criticism had the operators taken advantage of opportunities which familiarity with prothetical methods would have revealed to them.

The time has arrived when this subject should receive more thought and when prothetical knowledge should be more widely disseminated.

I can see in the not very distant future the subject of prothesis embraced in the curricula of the schools and colleges of surgery, when a graduate will be equipped with all the information requisite to guide him to not only amputate properly, but to put the stump in the most favorable condition for the prothetician; to take measurements, diagrams, and casts when necessary, to enable his patient to obtain a suitable appendage with the least delay; when his knowledge will enable him to detect defects in adjustment and to remove them; to prescribe changes that may be required in an artificial limb to accommodate changes that may take place in a stump. As surgeons will always be more numerous than leg makers, it is all the more important that their information on this subject should be broad and thorough.

I shall discuss the subject of Amputations Prothetically Considered from but a few standpoints, confining myself to amputations of the lower limbs only.

1. Length of Stumps.—Any stump that is well covered with integumentary tissue can not be too long. I am well aware that when I advance this proposition I antagonize the views of those artificial-limb makers who have not kept abreast of the times, and am controverting the rules that have been laid down by some writers of repute on the subject.

Artificial limb makers not many years ago, almost to a unit, decried the amputation of a leg below the junction of the lower and middle third, or "the point of election" so called, and were pronounced in their utterances against all ankle and partial foot amputations.

The methods which were then employed produced artificial legs that were not capable of adaptation to long stumps, particularly to stumps that extended to the ankles or below the tarsus. I may add that this adverse opinion on long stumps is still held by some protheticians, notwithstanding the fact that great departures have been made during the past decade or two in prothetical methods. When a leg maker of modern times says that an amputation should not be made below the point of election, you may regard him as confessing that he has not the ability to make a leg that can be worn on a long stump.

To-day artificial legs are made that can be worn on stumps of any length—tibiotarsal, mediotarsal, and tarsometatarsal not excepted. Any stump that is capable of bearing weight on the extremity is preferable to one that can not. A tibiotarsal amputation made after the method of Mr. Syme produces an end-bearing stump, and can be placed in the category of "the most favorable." An amputation after Dr. Pirogoff's method is also productive of an end-bearing stump, provided the os calcis is properly placed and united to the tibia or securely held in the intermalleolar space. An amputation in the tarsus or at the tarso-metatarsal junction after any of the methods of Cho-

part, Lisfranc, Hancock, or Hey, is productive of a stump that is capable of being treated prothetically.

In every partial foot amputation care should be exercised to prevent the contraction of the tendo Achillis; usually lashing in a suitably contrived splint will suffice. If this means will not accomplish the object, either tenotomy or fixation of the ankle joint should be resorted to, for if the heel is allowed to draw up and the amputated surface point downwardly, the possessor of that stump will be obliged to have an artificial leg applied that will not touch, but that will shield the amputated surface. This means that the artificial leg will elongate that side and necessitate the wearing of a thick sole and heel on the shoe worn on the well or companion foot. Such a stump ceases to be an end-bearing stump and its disadvantages are apparent.

I have a horror for those modifications of Chopart's and Pirogoff's operations that do not provide flaps on which the weight of the subjects can be endured. A case was brought to my attention some years ago which I can opportunely refer to here. A young man, a farmer by occupation, residing in Vermont, had his foot crushed. Amputation was deemed necessary. A modification of Chopart's operation was performed. The stump that resulted presented the appearance of an inverted cone, the apex scantily covered with tissue and extremely sensitive. This stump was hopelessly an end-bearing stump, and had to be treated the same as if amputation had been made above the ankle. It is obvious that inasmuch as a Chopart's operation could not have been performed, a Pirogoff's or a Syme's, or even an amputation above the ankle, would have given the patient a much better stump. This illustrates the importance of amputating for an end-bearing stump in a way to save the continuity of bone and to obtain an ample flap, even if the tarsus has to be sacrificed.

The advantages of a totally or partially amputated foot, producing an end-bearing stump, over a leg amputation are many. The more important are the following:

- An artificial leg for an ankle or partial foot amputation costs only half the standard price of an artificial leg for an amputation above the ankle.
- 2. An artificial leg for any of the above end-bearing stumps does not incase as much of the leg and thigh as an artificial leg for an amputation above the ankle.
- 3. The possessor of a stump extending to the ankle can improvise a sheath with suitable pad on which he can rest his stump and walk tolerably well; or if his stump extends to the metatarsus and he has a portion of the plantar surface of the foot left, he can walk and get about quite well without any contrivance. These are vital considerations for the poor man, and should be regarded by the surgeon.

The most modern and approved artificial legs for ankle and partial foot amputations provide phalangeal support, which will readily be conceded is absolutely necessary to aid progression and prevent limping. The absence of phalangeal support is always felt by those who do without prothetical assistance.

malleolar space. An amputation in the tarsus or at the tarso-metatarsal junction after any of the methods of Cho-

dred legs to stumps that have followed tibiotarsal, mediotarsal, and tarso-metatarsal amputations. During the existence of the house of which I am a member (A. A. Marks) over fourteen thousand subjects, with amputations at various points of the leg, thigh, and arm, have been supplied with artificial limbs. Most of them have come under my personal supervision. With this experience I feel myself competent to say that long stumps with ample flaps, that stumps resulting from tibiotarsal, mediotarsal, and tarso-metatarsal amputations, can be supplied with artificial legs that will be comfortable and pleasant to wear, and that will restore the wearers to the amplitude of their usefulness.

A stump extending below the knee is preferable to a stump extending to the knee, provided the stump is capable of flexion and extension. If the stump is disposed to become extended and ankylosed, it will be preferable to sacrifice the leg to the knee.

I had occasion to share the regrets of a subject that was brought to my office not many years ago. This man's leg had been amputated about four inches below the knee articulation; the stump was extended and ankylosed. To make an artificial leg for him would necessitate a rigid knee in the artificial or an articulating knee out of parallelism by about four inches with the natural knee. Either would place the fellow at a disadvantage, especially when sitting. If in the amputation of this leg the operator had had any indication that his patient's stump would become extended and ankylosed, he would have displayed greater wisdom if he had amputated through the knee articulation. amputation below the knee should, as far as possible, be made with proper regard to the preservation of full knee mobility, and during the recuperative period the knee should occasionally be forced into action, so as to prevent impairment of the flexors and extensors.

A stump extending to the knee is preferable to a shorter stump. The condyles and nodules of the femur should never be excised in knee disarticulations. The nodules afford means for securing an artificial leg, and the condyles and articular surfaces are better prepared by Nature to endure pressure then the saw or the knife can prepare them.

If the patella can be placed in the intercondylar space and properly secured, it is always desirable to do so.

The foregoing, I hope, will serve as an appeal to every operating surgeon to sacrifice as little of the human limb as possible, giving a proper regard to the securing of integumentary tissue for the purpose of covering the extremity and protecting the partly excised bones. These are certainly the teachings of the wisest and most conservative surgeons of the past, and I know of no reason why they should now be relegated to obsolescence.

2. Flaps.—All stumps should be provided with ample flaps; not redundant flaps. A redundance of tissue on the extremity of a stump is no advantage. The prime office of a flap is to protect the extremity of the bones, and they should be only ample to effectually perform that function; whether the flaps are anterior or posterior, exterior or interior, or a combination of any of the four, it matters not, so long as the extremities are well protected. Periosteal flaps

are desirable, as they give additional protection to the bones and prevent integumentary flaps from becoming adherent to the bones.

If an amputation is to be done below the middle third of the leg, bone should be sacrificed in order to obtain suitable flap. If the amputation is to be made above the middle third, bone should not be sacrificed, even if transplantation is necessary in order to secure flap. Every inch of healthy bone above the middle third is desirable for leverage purposes. If a thigh amputation is to be done close to the knee, bone can be sacrificed in order to secure flap. The nearer the amputation is to be done to the body, the greater should be the care to save bone.

3. The Disposition of Cicatrices.—The rules established by all the accepted authorities on ankle and partial foot amputations should be rigorously observed. By so doing, the disposition of the cicatrices will be the most advantageous for prothetical purposes.

In all amputations of the leg and thigh as well as knee disarticulations the cicatrices should, as far as possible, be placed well away from the extremities of the bones and preferably along the posterior aspects. Contiguity or adhesion of the cicatrix with the extremity of a bone is frequently the cause of suffering.

4. Treatment of Stumps after they have become Healed. -A stump, before it is called upon to perform the functions of operating an artificial limb, is an inactive remnant of an active member of the body. On account of its inactivity, it becomes disposed to accumulate adipose tissue, and, if permitted to do so, it will become abnormally large and ædematous. If possible, this growth or condition should not be permitted. Usually tight bandages will prevent it. The bandages should be applied from the time the stump has healed until the artificial leg is applied. The bandages should be as tightly drawn as possible and not interfere with circulation. The bandages should be applied in the usual way, beginning at the extremity of the stump and continued the entire length of the complete section of the limb above the stump. This means for a partial foot amputation that the bandage should be carried to the knee, and for a leg amputation that the bandage should be carried to the body.

I have frequently met surgeons who incline to the belief that an attenuated stump should be allowed, and in fact encouraged, to grow so as to possess the dimensions of the companion leg before an artificial limb is applied. This certainly would be desirable if such growth would permanently and effectually resist the influence that an artificial leg will exert on the stump to reduce it.

It can be stated for a certainty that an artificial leg will harden, solidify, and diminish any stump. In consequence of this, it is desirable to keep the stump as small as possible so as to minimize the changes that will follow the application and wearing of a leg.

5. Time to apply an Artificial Leg.—It will be safe to apply an artificial leg to a stump that has resulted from traumatic causes as soon after the healing of the stump and the recovery of the patient to his normal vigor as possible. Nothing can be gained by waiting beyond that time.

Waiting entails a loss of time and permits the stump to become enervated from disuse.

A stump that is the result of disease, especially if of a malignant nature, should be obliged to wait until there is a certainty that the pressure, confinement, and concussion that follows, more especially the initial operations on an artificial leg, will not excite a recurrence of the disease.

A child who has lost a leg is never too young to have an artificial leg applied. It should be observed that the tissues, bones, and articulations of an infant or a growing child must be forced into action in order to become developed, healthy, and vigorous.

To hobble about on one crutch or a pair of crutches for a number of years is rather a severe and inhumane punishment to impose on a child because he is growing. An artificial leg of modern construction can be lengthened from time to time at a very slight expense, and as an artificial leg provides the nearest approach to a natural prop for the amputated side, it is the only means that will encourage healthful growth and symmetrical development.

To illustrate this fact, I can do no better than present the case of an infant brought to me by Dr. Bacon, of New Haven, Conn. The child was not quite nine months old when I took her in charge. Her leg had been amputated two inches below the knee for congenital causes. The stump tended to flex and remain so; ankylosis was feared. I applied a neat-fitting leg with knee articulation. The artificial leg held the stump in extended and flexed positions, according to the manner in which the child was held or placed. In a few months the child began to creep, a few months later she was able to stand, and later still she learned to walk. The artificial leg assisted her in all these operations of progression. She developed rapidly and symmetrically, and to-day she is a young lady of comely proportions, enjoying good health, walking as gracefully as one in possession of Nature's limbs-a testimony of the wisdom of applying artificial limbs to the young when misfortune has deprived them of their share of extremities.

The Syracuse Academy of Medicine.—The medical profession of Syracuse, New York, having outgrown their old City Medical Association, have made a complete reorganization of it and call their new society the Syracuse Academy of Medicine. They have obtained permanent quarters which have been newly furnished to meet their needs, and a library and reading room are new features. A bequest of \$500 from the late Dr. Shipmam is to form the nucleus of a library. The whole profession have entered into the new organization with an enthusiasm and unanimity that assure a successful future. Regular meetings will be held on the first and third Tuesday evenings of each month. The following officers have been elected for the present year: President, Dr. H. D. Didama; vice-presidents, Dr. Alfred Mercer and Dr. John Van Duyn; secretary, Dr. T. H. Halsted; treasurer, Dr. E. L. Mooney; members of the council, Dr. Ely Van de Warker and Dr. N. P. Warner; trustees, Dr. J. L. Heffron, Dr. H. L. Elsner, Dr. R. C. McLennan, Dr. D. H. Murray, and Dr. F. H. Stephenson.

The New England Society of the City of New York.— Dr. William 'N. Hubbard has been elected a member of the medical board. THE

NEW YORK, SATURDAY, JANUARY 27, 1894

ANOTHER BILL FOR A BUREAU OF PUBLIC HEALTH.

Each year witnesses the introduction into Congress of some bill intended to provide for national supervision of the public health, and it is scarcely a matter of surprise that a bill has been introduced into the present Congress that has for its purpose the establishment of a bureau of public health within the Treasury Department of the United States. This bill, number 4833 in the House and number 1153 in the Senate, aspires to a completeness and comprehensiveness that are likely to mislead many who may not have followed the trend of sanitary legislation in this country. It speciously presents good features that are not new, although they have been less than a year upon our statute books, while it proposes new measures that do not seem to us to be good.

The first section of the bill divides most of the United States into nine sanitary districts, each district to have one representative in the bureau. Here we note the curious feature of the largely populated States of Illinois, Indiana, Michigan, Ohio, and Wisconsin, with their diverse and important sanitary interests, having no more representation and supervision than the sparsely populated States of Idaho, Minnesota, Montana, North Dakota, and Washington and the Territory of Alaska. To present the matter more forcibly, a district having a population of little more than two million inhabitants, a total that is less than the population of each of the first-mentioned States except Wisconsin, is to receive the same expert attention as one having a population of almost thirteen millions and a half. Perhaps this is because of the justifiable faith of the formulators of this bill in the admirably organized boards of health, and it is not an invidious distinction to refer particularly to those of Michigan and Illinois, in the first-mentioned district of States.

We said that most of the States were provided for in the bill. This was because Louisiana, that has the proud distinction of originating the modern system of maritime quarantine, is not referred to in any of the sanitary districts mentioned in the bill. Are we to conclude that, therefore, she does not require the supervision of the general government?

The second section of the bill provides for the creation of a bureau of public health, to consist of a commission of fifteen, eleven of whom shall be appointed by the President, and the four others to be the surgeon generals of the army, the navy, and the Marine-Hospital Service and an officer from the Department of Justice. As these officers are to be under the direction and supervision of the Secretary of the Treasury, we are surprised to note-the omission from the bill of repealing sections of those statutes that give the Secretary of War and the Secretary of the Navy exclusive jurisdiction respectively

over the surgeon general of the army and the surgeon general of the navy. Furthermore, one surgeon general of the army has placed himself on record as opposed to medical officers of the army having anything to do with quarantine duty, and it is possible that the present incumbent will feel that his subordinates can be actively occupied in the performance of their military duties. It will, be seen that these two sections are but an enlargement of the provisions of the defunct National Board of Health law.

The third section provides for the organization of the commission, and it is remarkable that this apparently representative body is compelled to select one of the two members at large as president, while the other becomes vice president. In other words, the nine representatives of all the States are not privileged to select one of their number as their presiding officer. Furthermore, while the members in general have but three years to serve, each of the members at large serves for six years. As it is evidently the intent of this section to provide for the selection of new members each year, it is not apparent why any discrimination is made in favor of the members at large, or why they, more than the others, should be specially favored. The president of the board has authority to call special meetings of the members, and there is to be an annual meeting every October.

The fourth section provides for an executive committee that consists of the commanding officers of the medical departments of the government, the commission's president, and the Department of Justice official. The commission's vice president is omitted from this committee.

The fifth section authorizes the commission to have conferences with officers of State boards of health. We fancy that with such a commission these conferences would be as frequent as the Greek kalends.

The sixth, ninth, tenth, eleventh, twelfth, thirteenth, fourteenth, fifteenth, sixteenth, seventeenth, eighteenth, nineteenth twentieth, twenty-first, twenty-second, twenty-third, twentyfifth, and twenty-sixth sections are nothing but the present national quarantine laws with slight changes in phraseology.

In fact, the entire bill is devoted to border and inter-State quarantine, with the exception of section seven, that provides for investigations into the nature, origin, and prevention of contagious, epidemic, and other diseases.

In other words, Congress is asked to re-enact the quarantine act passed February 15, 1893, and to substitute for the present single executive a heterogeneous collection of medical men. Presumably the reason for this is that the responsibilities of the office are too great for one man. If this is so, why not fifteen Presidents, or ten Secretaries of the Treasury, or half a dozen judges of a court at one and the same time? Out upon such logic! It is a plea for more, not better, officeholders and for greater extravagance in the disposition of public funds.

This bill would abrogate existing legislation and give us nothing better. In place of the Marine-Hospital Service, that has demonstrated its efficiency, and whose corps of officers constitute the only large body of medical men in this country that

has been trained in sanitary laws and methods, we are to have a commission whose members will necessarily often be appointed as a result of political influence, and consequently whose knowledge of hygiene will be less than that of the interest they are likely to display in dispensing patronage. The men that would be qualified to fill such positions could not afford to jeopardize their practices by accepting them, and the men that would scramble for these offices are not desirable. The political doctor is likely to know his politics better than his medicine.

This proposed law, in its very nature, will not receive the support of the medical profession of this country, and we can not suppose that Congress will 'pass it in its present form, increasing as it does the number of officials and that of salaries without a corresponding increase of means for the protection of the public health.

#### MINOR PARAGRAPHS.

#### FRACTURE OR DISLOCATION?

A suit for malpractice against a well-known physician of Brooklyn has recently been publicly noticed. The complainant, at one time a hospital nurse, suffered from a fall down a long and steep flight of stairs. An injury of the arm resulted, which the defendant diagnosticated to be a fracture. The treatment was by means of splints at first, and a plaster dressing soon afterward. The patient states that the suffering increased to such an extent that she deserted her physician and resorted to the City Hospital, where she had formerly been on duty as a nurse. At that hospital, it is further stated, the house surgeon declared that the injury was not a fracture but a dislocation. There is promise of an acrimonious discussion in court, as is too apt to be the case in questions of this nature, over the diagnostic points and the severity of the damage. We may expect an ultimate vindication of the practitioner, but he will be ground between the upper and the nether millstones of misrepresentation and law-costs.

#### THE MEDICAL MISSIONS OF GREAT BRITAIN.

The compiler or editor of Whitaker's Almanac for 1894 has collated some statistics concerning medical men in foreign fields. It states that there are 359 fully qualified physicians serving the various missionary societies. Seventy-four of them are women. There are sixty mission hospitals in China. That at Canton has a hundred beds, and the Swatow hospital has about the same number, while that at Srinagar, in the Vale of Cashmere, has eighty. The Free Church of Scotland alone sends out not fewer than twenty-five medical missionaries, many of them men of commanding ability.

#### DEATH IN AN ATTEMPT TO WIN A WAGER.

The London correspondent of the American Practitioner and News tells of a man who, in an English ale-house, made a bet that he could take a billiard-ball into his mouth and close his lips over it. He made the attempt and seemed to have accomplished the feat. He was seen to struggle, however, and died by suffocation while being taken to a hospital. At the inquest it was found that the billiard-ball had been crowded back so far as to obstruct the upper lumen of the larynx, while the epiglottis was not seen to be depressed. The organs of the body were healthy but congested.

#### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 23, 1894:

DISEASES.	Week ending Jan. 16.		Week ending Jan. 23.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	()	0
Typhoid fever	- 6	1	7	7
Scarlet fever	113	13	116	9
Cerebro-spinal meningitis	0	()	0	4
Measles	473	24	606	50
Diphtheria	187	52	225	65
Small-pox	8	-9	27	3

The Medical Society of the State of New York.—The "delegates' train" for Albany will leave the New York Central and Hudson River Railroad station on Monday, February 5th, at 3.30 p. m. Those who wish for seats in the private car should notify Dr. Alexander Dallas, of No. 65 West Thirty-sixth Street.

The Medico-chirurgical College of Philadelphia has created three new clinical chairs, viz.: Genito-urinary surgery, orthopædic surgery, and otology. These, together with the vacancy in the chair of clinical medicine, will be filled permanently at the end of the present session.

The New York State Medical Association.—The tenth annual meeting will be held in Brooklyn on Tuesday, May 22, 1894. All fellows desiring to read papers will please notify the secretary, Dr. E. H. Squibb, P. O. box 760, Brooklyn.

The Philadelphia Board of Health.—Dr. Myers, of that board, has recently reported that diphtheria may be prevented by the inoculation of a protective serum. It is announced that the next number of the *Therapist* will have the full text of that report.

The Pauper Insane of Queens County.—The removal of the lunatic poor—forty-three males and forty-five females—of Queens County was recently effected. They were taken a part of the way by special train from the asylum at Mineola, and part of the way by stages. Twenty male and ten female nurses were in charge of them.

The Brooklyn Health Commissioner's Office.—It is announced that the new commissioner, Dr. Z. Taylor Emery, has appointed Dr. Richard M. Wyckoff deputy commissioner, Dr. George E. West secretary, and Mr. Alexander H. Van Cott counsel.

A Parisian Honor to a Physician's Memory.—We learn from the Progrès médical that the rue des Fontis has been named the rue Blanche, in honor of a deceased physician of that rows.

#### Society Meetings for the Coming Week:

Tuesday, January 30th: Medical Society of the County of Onondaga (semi-annual—Syracuse), N. Y.; Boston Society of Medical Sciences (private).

WEDNESDAY, January 31st: Auburn, N. Y., City Medical Association; Middlesex, Mass., North District Medical Society (Lowell); Gloucester, N. J., County Medical Society (quarterly); Berkshire, Mass., District Medical Society (Pittsfield).

THURSDAY, February 1st: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the

Village of Canandaigua, N.Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, February 2d: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, February 3d: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

## Wetters to the Editor.

THE GALVESTON COUNTY, TEXAS, MEDICAL SOCIETY.

GALVESTON, January 18, 1894.

To the Editor of the New York Medical Journal:

Sir: The old so-called Galveston County Medical Club was reorganized the year before last under the name of the Galveston County Medical Society, which is now composed of the most earnest members of the medical profession of this city and vicinity. The strife, political and other, under which the profession here had been unfortunately laboring for quite a number of years is fast disappearing. Hopes are entertained, with good foundation, to the effect that the new corporation may be a bond of union, harmony, and good will for the medical fraternity of this city, the majority of whom are firm believers in, and faithful observers of, the code of ethics of the American Medical Association.

During the year just closed several papers were read before the Galveston County Medical Society, which have been published in medical periodicals, especially the *Texas Medical* Journal, the official organ of the society.

At the regular meeting of the society, held November 6, 1893, the following officers were elected for the current year: President, Dr. William Keiller; vice-presidents, Dr. A. F. Sampson and Dr. J. E. Thompson; treasurer, Dr. W. H. Baldinger; secretary, Dr. David Cerna; executive committee, Dr. A. J. Smith, Dr. R. C. Hodges, and Dr. Edward Randall.

At the meeting of the 20th of November, 1893, Dr. John B. Haden read a paper entitled The Visual Field and the Perimeter, which elicited an animated discussion participated in by Dr. A. J. Smith, Dr. R. C. Hodges, Dr. J. E. Thompson, and Dr. W. Keiller. At the meeting of the 4th of December two papers were presented, one on Uterine Hæmorrhages, by Dr. William Keiller, and one on Vomiting in Pregnancy, by Dr. George H. Lee. Both papers were extensively discussed, the first by Dr. B. E. Hadra, Dr. J. E. Thompson, Dr. H. A. West, and Dr. A. F. Sampson, and the second by Dr. B. E. Hadra, Dr. A. G. Clopton, and Dr. D. Cerna.

Dr. Keiller wrote on the hæmorihages occurring in abortion, extra-uterine pregnancy, uterine or cervical polypus, fibromyoma, inversion of the uterus following parturition or the result of an effort at expulsion of a pedunculated fibroid, and sarcoma and carcinoma, describing separately the diagnosis and treatment. The author thought that, with reference to the treatment of cancers, in epithelioma of the cervix where the whole disease could be removed by supravaginal amputation of the cervix, that operation was to be preferred to hysterectomy, as the results were exceedingly good and the risks very small. Where the disease had gone further than could be reached by this method, but had hot spread to the broad ligaments, vaginal walls, or bladder, vaginal hysterectomy by ligature, or by clamp

if the ligature was impossible, was the proper treatment. The results were as good as for cancer of the mamma, most patients having at least a period of comparative health. Where the complete removal of the disease was impossible, hemorrhage and the fector of the discharge might be kept in check by the curette or thermocautery and iodoform tampons.

In discussing the paper, Dr. H. A West, referring particularly to the treatment of hæmorrhage due to abortion, said that there was a certain number of cases, and they were too apt to recur repeatedly in the same woman, in which the fœtus was expelled, yet the afterbirth remained firmly but partially attached, and there was furious bleeding from the open mouths of some uterine sinuses. What was to be done under such circumstances? The answer to this question was not always easy. The paramount indication would appear to be to remove the retained placenta which was the cause of the hæmorrhage. But how and when was this to be done? Who had not experienced the difficulty in extracting a placenta or an ovum when the os was contracted so as barely to admit one finger? The difficulty was still greater when there was more or less complete detachment. If one gave chloroform and attempted to break up and remove the foreign matter piecemeal with the finger or curette, portions were likely to be left behind, and were a certain source of future trouble. He believed that it was better practice, unless we were certain that we could remove the entire uterine contents, to tampon the womb as well as the vagina thoroughly with iodoform gauze, which would control the bleeding and give a little time for Nature to separate the adherent mass from the uterine wall, when it would often be expelled spontaneously, and, if not, its removal with finger, forceps, or curette became a comparatively easy matter.

Dr. A. F. Sampson could not agree with those who said that · ectopic pregnancy was easily and rapidly diagnosticated. He admitted that when this form of pregnancy had been going on for two months, or rupture of the sac, with its attending shock, had taken place, it was an easy matter, but not so in the first weeks of ectopic gestation. To illustrate: He had been called to a case at midnight in the latter part of September. There was no evidence of any shock. The patient gave a history of delayed abortion. She had gone but a few days over her menstrual period, and had had uterine pains and some hæmorrhage for the preceding three or four days. From what he could gather, he believed the product of conception had passed, and the pains that were referred to the uterus were due to the partially retained placenta, etc. He prescribed ergot, quinine, and hot vaginal douches. There was no abnormal temperature, the pulse was in the eighties, and no evidence of a serious condition was manifested. The patient seemed to progress satisfactorily for several days, though slight hæmorrhages kept up. Twenty days after his first visit, the patient not doing satisfactorily as to the flow, which still kept up and began to have an offensive odor, he had chloroform administered, dilated the cervix, and curetted. Before doing this he made a careful examination and detected no evidence of pelvic trouble except what he attributed to the endometrium. His patient seemed to have no immediate bad effects from the curetting; in fact, she seemed to improve to such a degree that he, in due time, allowed her to sit up. Later, pelvic cellulitis was set up and proved obstinate to treatment. A consultation was bad, and his diagnosis of pelvic cellulitis was confirmed, as by that time a mass had developed in the right pelvic region. Later still this woman passed out of his hands and became the patient of a most skilled surgeon, whom he had kept well informed as to the progress of the case. Shortly after taking charge of the case, the attending physician suspecting that an abscess had developed which seemed to point toward the vault of the vagina, opened up what he expected to find a pelvic abscess, when lo! a gush of blood, with a profuse hamorrhage following, proved it to be a case of ectopic pregnancy.

Dr. J. E. Thompson related a case of extra uterine pregnancy at the fourth month in which all the signs of pregnancy but that of hæmorrhage were present. A complete decidua was passed at the second month. A tumor was found occupying a position to the left of the uterus; it was freely movable, was of the size of an orange, and could be completely explored. An operation was done at the fourth month, and the tumor completely removed without difficulty. It proved to be a gestation in an ovarian sac; no fœtus was present, but placental villi were found microscopically.

In the discussion of Dr. Lee's paper, the idea seemed to prevail that washing out the stomach with warm sterilized water, in preference to the administration of drugs or even to operation (of course, in exceedingly rare cases), was the most rational method of treatment in a large number of cases of vomiting in pregnancy. Dr. Lee did not entirely agree with this idea, and thought that in many cases an operation was most urgently demanded.

At the meeting of the 18th of December Dr. James Kennedy read a paper entitled Traumatism as a Factor in Uterine and Ovarian Pathology. He made the point that traumatism was the most common factor in the production of pelvic disease, and reported cases apparently in support of his assertion. In discussing the paper, Dr. B. E. Hadra said he believed that traumatism produced lesions anywhere provided the field was prepared beforehand. He did not believe that traumatism per se could produce inflammation of the pelvic organs. Even in virgins apparently healthy otherwise he assumed that traumatism produced disease when previous infection had occurred in one way or another. Dr. W. Keiller called attention to cystic degeneration, which by itself, he thought, meant nothing, since it could be confounded with healthy enlarged follicles of the ovary. He agreed with Dr. Hadra in not considering traumatism as a factor by itself in causing pelvic troubles. He did not believe that leucorrhea, for instance, could be made a ground for diagnosis of septic or non-septic inflammatory processes. In closing the discussion, Dr. Kennedy persisted in the belief that traumatism, by interfering with nutrition, was alone sufficient to cause structural degenerative changes of the parts, even in the absence of germs, without producing suppurative processes. Dr. Hadra replied by saying that he did not believe that cystic degeneration was necessarily the result of inflammatory processes.

There was a large attendance at the meeting held on the 15th inst., when Dr. Edward Randall read a very interesting paper on Acute Anterior Poliomyelitis, and reported several cases. From a close study of these cases he held the view that the disease was infectious. The discussion was a very spirited one and tended to the support of Dr. Randall's idea of infectiousness in regard to the disease under consideration. But, since this communication is already too long, I will refrain for the present from giving you any details relating to this interesting question.

At the next meeting of the society, to be held on the 22d inst., besides the reading of papers by Dr. A. F. Sampson and Dr. A. J. Smith, the subject of Code Revision will be introduced, and an interesting discussion on this matter is expected. To judge from the attitude of the majority of the members, some of whom have already expressed opinions, there is scarcely any doubt that no revision will be recommended.

I will endeavor to keep you informed in regard to all matters of general interest to the profession.

## Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of January 18, 1894.

The President, Dr. D. B. St. John Roosa, in the Chair.

Observations on Excessive Intestinal Putrefaction.—Dr. C. A. Herter read a paper with this title. The author stated that the facts brought to light two years ago regarding the occurrence of excessive intestinal putrefaction in epileptics had stimulated an inquiry into the occurrence and character of putrefactive processes in the intestine in other conditions than epilepsy. This inquiry, which had been carried on for two years, made it clear that deviations from the normal character and degree of putrefaction in the contents of the intestine were met with in association with a variety of morbid states. The objects of the paper were, first, to present the evidence as to the existence of putrefactive processes; second, to enumerate and discuss the clinical conditions in which putrefaction occurred in excess; and, third, to state the principles that should enter into the management of such cases.

It had long been known that a variety of aromatic substances, including indol, phenol, etc., were produced in consequence of the action of anaerobic bacteria upon proteids, and it was also known that this process of putrefactive decomposition occurred normally to some extent in the human intestine when nitrogenous food was introduced. In 1880 a very important fact was brought to light by Baumann-namely, that the various aromatic bodies, however formed within the intestine, were at last eliminated from the body (if absorbed) through the urine, almost exclusively in combination with sulphuric acid, in the form of ethereal sulphates. The ethereal sulphates therefore became an index of the amount of putrefactive products absorbed from the intestine, and the determination of their amount in the urine was the best indication we had as to whether the putrefactive processes were or were not in excess. This fact constituted the basis of the present investigation. For a full presentation of the evidence which had established this fact the reader was referred to the original article.

Careful observations had been made by the author, with the aid of an expert chemist, upon the ethereal sulphates in forty cases of epilepsy, eight cases of melancholia, eight cases of Bright's disease, and in a number of cases of anæmia, pernicious anæmia, leucocythæmia, catarrhal jaundice, exophthalmic goître, and many other diseases. In the case of epilepsy, about two thirds of the cases of grand mal showed distinct evidence of excessive putrefaction. In a few cases there had seemed to be a distinct relation between this excess and the occurrence of seizures, and in several there was a reduction in the number of attacks when the ethereal sulphates were reduced by treatment. The cases of melancholia showed a striking increase in the ethereal sulphates in five instances. The question arose in regard to such cases whether the excessive intestinal putrefaction might or might not be due, in some instances at least, to the partial starvation that existed in many cases, for it was now well known that inanition caused a great excess in the putre factive products. In two cases of typical mania the sulphates had been normal. Six of the cases of chronic Bright's disease showed a marked increase in the sulphates. A considerable excess of the putrefactive products was found in many cases of simple anæmia, but in many the amount was normal.

From a study of many cases of intestinal indigestion the author had reached the conclusion that putrefactive excess was frequently present in these conditions. It was observed that

there was often a close relation between persistent intestinal flatulence and the occurrence of indigo-blue, usually in moderate amount, in the urine. In many of these cases the indigo blue disappeared when the patient was put upon a suitable diet. It seemed probable that in such cases the over-production of indican depended on a condition of chronic catarrhal inflammation at some part of the intestinal tube, probably the duodenum. Many of the symptoms were related to the disturbances of nutrition that resulted in excessive elimination of uric acid, such excess being frequently found in intestinal indigestion associated with an excess in the ethereal sulphates, or with indigo-blue, or existing by itself. It was probable that the symptoms depended to a large extent upon the action of the substances formed in the intestine during the putrefaction of proteids coincidently with the formation of the aromatic substances which were eventually excreted by way of the kidney.

The author deduced the following conclusions as a result of his investigations: 1. An excess of the ethereal sulphates in the urine was evidence of excessive putrefaction of proteids in the intestine. There were two exceptions to this statement: first, in the case of suppuration without free drainage; second, where certain drugs, such as creasote and salol, had been administered. 2. The indigo-blue of the urine was not necessarily proportional to the ethereal sulphates, and was to be regarded as due to a special form of putrefactive decomposition. 3. The regular occurrence of more than a trace of indigo-blue was to be regarded as pathological, although in robust persons there might be very little evidence of disordered digestion for a time. 4. The presence of indigo-blue in the urine of children was no evidence of the existence of a tuberculous process. 5. Intestinal flatulence was oftener associated with intestinal putrefaction than any other symptom of intestinal indigestion. Epigastric pain and tenderness, the sense of emptiness, and nausea, bore no relation to the ethereal sulphates. 6. Both constipation and starvation might increase the putrefactive products in the urine. 7. Epilepsy, acute melancholia, and chronic Bright's disease were usually associated with excessive intestinal putrefaction. 8. The treatment of excessive intestinal putrefaction by means of drugs was at present unsatisfactory. 9. The use of rare beef and of milk, and the exclusion, as far as possible, of vegetable nitrogenous food were important and effective means of reducing intestinal putrefaction and of relieving symptoms of intestinal indigestion. 10. The relief of intestinal symptoms could not be ascribed wholly to the effects of a milk-and-beef diet, for such diets reduced the excess of uric acid which was observed in many cases of intestinal indigestion. 11. The treatment of epilepsy by means directed to the intestinal condition led in many cases to a reduction in the number of the seizures and to marked improvement in the general health. 12. It was probable that in some cases of epilepsy in children the early seizures were determined by intestinal derangement, and that certain treatment directed to the correction of the putrefactive excess might greatly improve or even cure some cases of this kind, in the sense of preventing the establishment of the epileptic habit.

Dr. L. C. Gear said that he had been more than pleased to hear Dr. Herter's very original paper, and to find that so much was being done in the direction of determining what to do with that class of nervous diseases that came under no definite head. In regard to the treatment of such cases, the speaker's conclusions coincided with those of Dr. Herter, in that the remedies were very inadequate to cope with the condition. He had found that to correct the putrefactive changes in the intestine a combination of salol, bicarbonate of sodium, and pancreatin BOOK NOTICES.

gave the best results. Where there were chronic disturbances of digestion and a diarrhea had been set up, and where everything had failed, he had produced the best effect with calomel. Subgallate of bismuth also was beneficial. Rochelle salts, used in small doses continued over a prolonged period, acted well in disinfecting the intestine, the physiological effect on the capillaries being nearly the same as that of iron. He rather regretted, for his own information, that Dr. Herter had not given the amount of uric acid found in connection with intestinal putrefaction. In his own cases he had found that where patients were put upon a nitrogenous diet there was always an excess of uric acid. In regard to dietetic treatment for the nervous conditions arising from intestinal putrefaction, the speaker had been unable to obtain any good results.

Dr. C. L. Dana thought that Dr. Herter's scientific investigations had done much to stimulate the efforts of neurologists. His experience in the treatment of the class of cases described had not been very satisfactory. He had found in almost all the cases an excess of uric acid. He had adopted the method, as described some time ago by the author of the paper, for determining the indican in the urine. Putrefactive processes in the intestine caused one set of symptoms in children and another in adults-for instance, acquired neurasthenia was only present in the adult. The continuous investigation for the cause of neurasthenia could not help but be of ultimate benefit. Some years ago all such symptoms had been laid to uric acid, then to eye-strain, and now attention was being drawn to putrefactive changes in the intestine. A remedy that the speaker had found very effective in neurasthenic headaches, where everything else had failed, was naphthalin in doses of from sixty to eighty grains

Dr. W. H. Thomson was satisfied that much more could be learned of the functional nervous diseases from chemistry than from pathological anatomy, and that Dr. Herter's work was in the right direction. His experience with epileptics had been that before an attack the breath became foul and there was intestinal derangement with diarrhoa. Where the diet and intestinal condition could be corrected there was always a marked improvement in the character and number of the attacks and in the general health. In regard to intestinal antisepsis, there were very few drugs that could be depended upon. Salol was good, but it so frequently produced gastric disturbances that it could not always be used. Given in combination with benzoate of sodium, it gave the best results. He depended very largely upon bismuth in cases where there was much intestinal disorder, as in typhoid fever. It had been given continuously in the Roosevelt Hospital wards during the last siege of typhoid fever, with the result that in only one case had the diarrhœa been persistent. It could be combined to advantage with benzoate of sodium. One point which clinical experience had shown was that, so far, no diet list had satisfactorily corrected putrefactive changes in the intestine.

Dr. L. Emmett Holt said that there was one class of cases of patients that came under his notice suffering with undoubted intestinal indigestion. They were young children from one to four years of age with immense abdomens and generally rhachitic. These children had usually subsisted almost wholly upon a diet of carbohydrates, in the form of oatmeal. By placing them strictly upon a milk-and-meat diet, and excluding all starchy food, improvement was made rapid. The milk used was peptonized, and the meat in the form of rare beef scraped to a pulp. A dose of calomel was given every three or hour days to correct any constipation that might be present. He found that children could bear the limitation of food necessary to correct intestinal putrefaction much better than adults.

## Book Notices.

A Manual of Medical Treatment or Clinical Therapeutics. By I. Burney Yeo, M. D., F. R. C. P., Professor of Clinical Therapeutics in King's College, London, etc. With Illustrations. Vol. I. Pp. xiii-631. Vol. II. Pp. vi-744. Philadelphia: Lea Brothers & Co., 1893.

The author states that the object of this work is the study of disease from the point of view of treatment, a standpoint that is too often overlooked nowadays in the pursuit of researches in ætiology and pathology. Our first duty to our patients is to cure or to alleviate disease, and the successful physician is the one that best attains this goal.

As the author observes, it is clear that any or every part of the natural history of a disease may bear, directly or indirectly, on its treatment, and it would be most unphilosophical and uncilifying to discuss the therapeutics of a disease without at the same time considering the true nature of the phenomena we are endeavoring to control. He has accordingly striven, wherever it was possible, to deduce rational indications for treatment from an examination of the pathological nature and the clinical course and characters of the disease under discussion.

In the compilation of his material Dr. Yeo has avoided the tedious digressions of footnotes, although he disclaims any intention of making his pages suitable for "rapid reference," but rather insists that they are intended for thoughtful consideration. The treatment of disease by "rapid reference" is alien to rational therapeutics, for the rational indications for the treatment of disease and the data for accurate diagnosis are not arrived at by such a method.

The first volume considers the treatment of diseases of the organs of digestion, of those of the heart and blood-vessels, of those of the blood and ductless glands, and of those of the organs of respiration. The second volume deals with pulmonary tuberculosis, diseases of the liver, diseases of the kidneys and urinary apparatus, diseases of the nervous system, and constitutional and specific infective diseases.

We note with some surprise the position the author takes regarding the value of the modern methods of investigating stomach diseases. His remarks regarding the usefulness of lavage are judicious. There should be extended reference to direct electrization of the stomach—a procedure that is often of more value than lavage.

In the article on typhoid fever Dr. Yeo properly insists upon the necessity of intestinal antisepsis, and his remarks on the cold-bath treatment are most commendable.

To most of the chapters the author has added a number of formulæ employed by well known physicians.

The excellent scope of this work will insure it a wide and increasing popularity.

The Uniform System of Accounts, Audit, and Tenders for Hospitals and Institutions, with certain Suggested Checks upon Expenditure, and Tender and Other Forms for securing Economy, and the Index of Classification. Compiled by a committee of hospital secretaries, and adopted by a general meeting of the same, 18th January, 1892. By Herry C. Burdett. London: The Scientific Press, 1893. [Price, 6s.]

In this volume Mr. Burdett gives much useful information regarding the methods of keeping hospital accounts, and the forms suitable for proposals for supplies. The specifications for the quality of supplies are so precise that they would be equally

satisfactory to the contractor and to the steward. Hospital authorities will find this little volume very suggestive.

Essentials of Practice of Medicine. Arranged in the Form of Questions and Answers. Prepared especially for Students of Medicine, By Henry Morias, M. D., Late Demonstrator, Jefferson Medical College, Philadelphia, etc. With a very complete Appendix on the Examination of Urine, by Lawrence Wolff, M. D., Demonstrator of Chemistry, Jefferson Medical College. Colored (Vogel) Urine Scale and Numerous Illustrations. Third [Edition, revised and enlarged by some Three Hundred Essential Formulæ, selected from the Writings of the most eminent Authorities of the Medical Profession. Collected and arranged by William M. Powell, M. D., Attending Physician to the Mercer House for Invalid Women at Atlantic City, N. J. Philadelphia: W. B. Saunders's [1894. Pp. xv-17 to 374. [Price, \$2.] [Saunders's Question Compends]

That three editions of this, manual have been published is an evidence that it meets the wants of a number of students. Necessarily such a compend can not be exhaustive, but it seems that there should be some reference to acromegaly, auteriosclerosis, myxædema, and parasitic diseases. It is not apparent why tuberculosis, a general disease, should be included among the diseases of the lung tissue. Errors are made in the statements that hæmorrhagic malarial fever "is very amenable to treatment," and that "if it is treated from the beginning the prognosis [of congestive malarial fever] is favorable"; both these fevers pursue a rapid course and usually terminate in death.

The therapeusis is sometimes antiquated; under the treatment of pneumonia, for example, the author makes no mention of the use of strychnine, apomorphine, or oxygen inhalations.

But, as a rule, the information contained in the volume is accurate as far as it goes.

Die Krunkheiten der Mundhöhle, des Rachens und des Kehlkopfes. Mit Einschluss der Untersuchungs- und Behandlungsmethoden. Für praktische Aerzte und Studirende. Von Dr. Albert Rosenberg, 1. Assistenten an der Universitätspoliklinik für Hals- und Nasenkranke in Berlin. Mit 178 Abbildungen und einer lithogr. Tafel. Berlin: S. Karger, 1893. Pp. x-329. [Preis, M. 8.]

The author divides his work into three sections, the first being devoted to the diseases of the mouth, the second to the diseases of the pharynx, and the third to the diseases of the larynx. It has been his aim to provide a work that would give the most recent knowledge of the actiology, symptoms, diagnosis, prognosis, and treatment of each of the principal diseases of these parts. The scope of the volume is essentially practical and the book may be commended as a safe guide to the student and physician.

The Healing of Rodent Cancer by Electricity. By J. Inglis-Parsons, M. D., M. R. C. S., M. R. C. P. (Lond.), etc. London: John Bale & Sons, 1893. Pp. vii-82. [Price, 5 shillings.]

Those familiar with the author's published papers on the treatment of neoplasms by strong alternating galvanic currents will recall his theory that a local sore or tissue subject to chronic inflammation and irritation may become malignant in consequence of a constitutional defect or want of control by the nervous system over the active proliferation of cells that takes place during the reparative process. If this theory is correct, it is remarkable that ulcers of the leg do not more frequently become malignant.

The author, however, is prepared to accept the parasitic theory that has recently been exploited as an explanation of the cause of neoplasms. We agree with him in believing that either of these theories is more satisfactory than Cohnheim's inclusion theory.

The method of operating for the galvanic treatment of ro dent ulcer is to anæsthetize the patient, introduce two platinumpointed insulated needles into the tissue of the neoplasm, and turn on the current for a few seconds, increasing its intensity until, if necessary, five hundred milliampères are attained. The current is alternated and the position of the needles is changed so as to effect as great a destruction of tissue as is possible. The operation should not last as long as an hour, and in the case of small tumors it may be completed in a few minutes. The advantages of electricity are that it causes no pain, sensation being abolished in the ulcer for several days after the application; and there is no hemorrhage.

The author has found that a year's immunity can always be promised, with probability of a longer period, even in bad cases. The method seems to be a valuable addition to our remedial resources.

Ophthalmic Nursing. By Sydney Stephenson, M. B., F. R. C. S. Edinburgh. With Sixty-one Illustrations. London: The Scientific Press, 1894. Pp. xii-188. [Price, 3s. 6d.]

This is a very good book for a nurse who is about to engage in ophthalmic nursing. It furnishes an outline of ophthalmic work and of the services required from the nurse, so that after reading it she can enter upon her work with a certain amount of understanding. But it furnishes simply an outline, which can be filled in only by practical experience; it can not be relied on to educate a nurse so as to make her competent to assume the care of diseased eyes. If this is understood, the book is a valuable one to place in her hands.

#### BOOKS, ETC., RECEIVED.

A Text-book of the Physiological Chemistry of the Animal Body, including an Account of the Chemical Changes occurring in Disease. By Arthur Gamgee, M. D., F. R. S., Emeritus Professor in the Owens College, Victoria University, Manchester, etc. With Two Chromo-lithographic Charts by Spillon and Wilkinson. Vol. II. The Physiological Chemistry of Digestion. London and New York: Macmillan & Co., 1893. Pp. xix-4 to 528. [Price, \$4.50.]

Outline of Physical Diagnosis of the Thorax. By Arthur M. Corwin, A. M., M. D., Demonstrator of Physical Diagnosis in Rush Medical College, etc. Chicago: The W. T. Keener Company, 1893. Pp. viii-9 to 111.

The Technique of Post-mortem Examination. By Ludvig Hektoen, M. D., Pathologist to the Cook County Hospital, Chicago, etc. With Forty-one Illustrations. Chicago: The W. T. Keener Company, 1894. Pp. viii-172. [Price, \$1.75.]

Climates of the United States, in Colors. Popular Edition of Denison's Charts, with Additions. By Charles Denison, A. M., M. D., Denver, Col., Professor of the Diseases of the Chest and of Climatology, Medical College, University of Denver, etc. Designed for the use of Physicians, Tourists, Health Seekers, Farmers, and Schools. Chicago: The W. T. Keener Company, 1893. Pp. 47. [Price, \$1.]

Relation d'une épidémie de choléra. (Étude clinique et expérimentale.) Par MM. A. Mairet, professeur de clinique des maladies mentales et nerveuses, et F. J. Bosc, chef de clinique des maladies mentales, et nerveuses à la Faculté de médecine de Montpellier. Avec 4 planches et 11 tracés dans le texte. Montpellier: Charles Boehm, 1893. Pp. 6-98.

Spinal Curvature. Description of a new Form of Apparatus in Special Relation to the Necessity and the Nature of Mechanical Support for the Spine. By C. G. Gumpel, Orthopædist. London: T. Pettitt & Co., 1892.

Atony of the Stomach. By Julius Friedenwald, A. B., M. D., Baltimore. [Reprinted from the Medical News.]

A Case of Ankylostomiasis. By W. L. Blickhahn, M. D., St. Louis. [Reprinted from the *Medical News*.]

The Actions and Uses of Pental. By David Cerna, M. D., Pb.

D., Galveston. [Reprinted from the Medico surgical Bulletin.] The Pilgrimage and Civilization of the Toltecs. By David Cerna, A. M., Ph. D., Galveston. [Reprinted from the Transactions of the Texas Academy of Science.]

Establishing a New Method of Artificial Respiration in Asphyxia Neonatorum. By J. Harvie Dew, M. D., New York. Read before the New York Academy of Medicine, February 2, 1893. [Reprinted from the Medical Record.]

Transactions of the American Ophthalmological Society. Twenty-ninth Annual Meeting, New London, Conn., 1893.

State Board of Health. Report of Willis G. Tucker, M. D., Ph. D., Director State Laboratory. [Extract from the Twelfth Annual Report.] 1891.

State Board of Health. Report of Willis G. Tucker, M. D., Ph. D., Director State Laboratory. [Extract from the *Thirteenth Annual Report.*] 1892.

Ninth Annual Report of the Adirondack Cottage Sanitarium, Saranac Lake, New York. November, 1893.

Report of the Health Department of the City and County of San Francisco for the Fiscal Year ending June 30, 1893.

## New Inventions, etc.

A NEW SPECULUM.

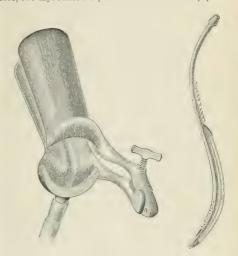

BY FRANK W. TALLEY, M. D.,

INSTRUCTOR IN GYNÆCOLOGY IN THE PHILADELPHIA POLYCLINIC.

The value of the copious use of water in the treatment of granulating wounds and of catarrhal diseases of the mucous membranes has long been appreciated by surgeons and by those who treat diseases of the nose and throat. Ulcers heal more speedily if they be washed with warm water at each dressing; and who would apply an alterative solution to a catarrhal nasal membrane without first having cleansed the surface of its altered secretions? For the successful treatment of uterine and vaginal conditions also the use of water is valuable.

In order that water may be freely used in the office treatment of gynæcologic patients without fear of wetting the clothing, I have had a funnel speculum made for me by Messrs. Charles Lentz & Sons, of Philadelphia. The instrument is a bivalve, hinged with a take-off joint and provided with a single screw for separating the blades. The blades are broader at the cervical end than at the vulvar end, overcoming the tendency for the instrument to slip out when used in relaxed vaginas and providing for a better exposure of the vault of the vagina. At the vulvar end the blades are considerably flanged, preventing the instrument from slipping too far into the vagina, when the vulva is enlarged by tears of the perinæum and protecting the vulva during the introduction of tampons from being soiled by the remedies with which they are smeared. The lower blade of the speculum is guttered and terminates at its vulvar end in a funnel, by which fluids may be conveyed through a rubber tube to a receptacle placed at the foot of the table or chair.

A speculum with a similar provision for conducting away fluids has been described by Dr. Davis in the New York Medical Journal for November 4, 1893. I can claim priority, however, having exhibited my speculum before the Philadelphia Obstetrical Society at its regular meeting held November 2, 1893, two days before the publication of Dr. Davis's paper.

It is my routine practice in the office treatment of my patients after inserting the speculum to wash the cervix and vault of the vagina with a stream of warm alkaline solution from a fountain syringe suspended upon the screen at the side of the examining table. The solution used consists of two drachms of sodium bicarbonate and thirty minims of carbolic acid to the quart of water at a temperature of 100° E. After all the mucopurulent discharges have been dissolved and washed away, the cervix and vaginal vault are dried with a few bits of absorbent cotton and a clean surface is afforded for the reception of the remedies used. Should it be desirable to scarify the cervix, the stream of warm water will favor a greater depletion and the blood will be carried away with the water into the slop jar below.

I believe that the speculum will greatly add to the convenience of treatment of these cases. The rim of the funnel has been so constructed as not to occlude the lumen of the instrument, and the addition does not materially add to its weight. The instrument may therefore be used whenever a speculum is needed.

1234 SPRUCE STREET.

## Miscellany.

Disorders of the Menopause and their Treatment.—M. Eloy, writing in the Revue générale de vlinique et de thérapeutique for December 28d, remarks that the part played by the change of life has hardly been adequately treated of in general pathology. At the present day we hear less of it than ever, but that does not do away with a good deal being said about the management of the disorders incident to that time of life.

Every practitioner is now and then consulted on the subject. He has to give very precise instructions in order to put Lis patient on her guard against the exaggeration of popular prejudices. Sometimes the condition of things is obscured, but it must be elucidated. Recent clinical works, among which are those written by Elliot in England, Jacobs in Belgium, and others in France and elsewhere, have drawn attention anew to this old question of practice. There is therefore an opportunity of drawing a therapeutical lesson truly useful to practitioners. One point seems to have been thoroughly made out; it is admitted that there is such a thing as a treatment of the menopause. It is preventive and curative of the accidents pertaining to it. It is a general treatment. Like any other, it should be hygienic primarily, and symptomatic as occasion requires.

The Hygienic Treatment of the Menopause .- So far as this is concerned, there is a perfect agreement between clinicians and physiologists. We have to take into account the diet, physical exertion, and the clothing. It may seem commonplace thus to enumerate these things, but it is useful. Sobriety in everything, according to Jacobs, is the moral principle that should inspire a woman at the change of life. As regards diet, physicians should advise in general white meat, eggs, milk, vegetables, and drinks but moderately alcoholic, pure water or wine diluted with water. The patient should avoid hearty meat, culinary refinements, coffee, tea, and stimulants. But this broad and vague prescription is not enough; we should take into account the old idea of temperament, although at the present time this idea is not very definite. To the plethoric a rather innutritious diet should be given: leguminous vegetables, white meat, and fruit; to the lymphatic, on the other hand, a sustaining and substantial diet: dark meat, fish, and generous wines in preference to milk and starchy articles of food.

The hygiene of sleep should consist in devoting only eight hours of repose to the plethoric and in combating the well-known tendency of lymphatic persons to sleep late. Jacobs advises them to rise early and to sleep on a moderately soft bed.

As regards physical exercise, for the plethoric we may recommend a walk after eating and for the lymphatic after bathing, in order to excite lively reaction; for nervous persons we should prescribe a daily course, sufficiently long, of walking and exercise. In the matter of dress, flannel should be employed for the plethoric, and for others lighter articles. Of course, regard is to be paid in this matter to variations of tem\_ perature; the clothing should be warm in winter and light in summer. The chemise should be of cotton rather than of linen; there should be only moderate lacing or none at all if there is a disposition to fleshiness, and the patient should wear shoes that are light but sufficient to protect the feet from dampness and chilliness. Hygienists deprecate chilling at the time of the menopause; it seems that cold is, as it were, the chief rathogenic factor of the complications that may arise. To sum up, the preservation of health at this period of life depends on the proper course of diet, hydrotherapeutics, graduated physical exertion, and gymnastics.

Jacobs urges the avoidance of excess in sexual intercourse. He remarks that it gives rise to debility and to local troubles, such as menorrhagia. After the critical age is passed, however, more freedom may be allowed.

Treatment of the Accidents of the Menopause.—The best-known of these are chlorosis, neurasthenia, and nervous and gastro-intestinal troubles. The chlorosis of this period was called by Canstatt "chlorosis of involution"; according to M. Germain Séé, it is anæmia dependent on the hæmorrhages or the affections of the heart that are common at this age. M.

Hayem, however, has pointed out that this interpretation, although sometimes exact, is not always so. There are cases in which, independently of casual causes, this anæmia excited by the menopause is a return to the chlorosis that the patient had previously been a subject of at the time of puberty. This statement is justified by clinical observation. Prominent with chlorosis are dyspeptic symptoms at the time of the menopause. The variety of these gastro-intestinal troubles is well known. At the time of the menopause a woman readily becomes chlorotic as the result of digestive disorders. Therefore, before prescribing iron or arsenic, the judicious physician will treat the stomach and intestines.

Loss of appetite is to be treated with tonics and bitters, such as nux vomica, gentian, etc. They should be given before eating and in the form of tincture. Of a mixture of equal parts of tineture of nux vomica and tineture of anise, from ten to fifteen drops may be taken before eating. Another prescription is: Three parts each of Hoffmann's anodyne, tincture of anise, and tincture of rhubarb, and one part of tincture of nux vomica. Potain recommends twenty drops of this in a little water before meals. In case of flatulence it may be preferable to prescribe powders, such, for example, as the following, recommended by Hérard: Powdered nux vomica, fifteen grains; powdered rhubarb, a drachm; chalk, forty-five grains; elæosaccharum of mint, a drachm. This is to be divided into twenty powders, one of which is to be taken before each meal. If there is dyspepsia it will be found that there is a deficiency of gastric juice; in that case Huchard's mixture may be prescribed-namely, hydrochloric acid, thirty drops; syrup of bitter-orange peel, an ounce; melissa water and linden water, each, two ounces. Of this a tablespoonful is to be taken after eating.

Another common accident, constipation, calls for particular notice. Coprostasis is to be prevented, for the purpose of avoiding intestinal self-poisoning, which has been shown to play an important part in the genesis of diseases characterized by faulty nutrition. One action of the bowels should be produced every day. As a laxative, aloes retains its faithful partisans; aloin conjoined with strychnine, a purgative with a tonic, is recommended by Elliot. A pill containing 0.15 of a grain of aloin and 0.075 of a grain of strychnine sulphate may be given once or twice a day. According to MM. Dujardin-Beaumetz and Huchard, senna is best given in the following mixture: Senna leaves, washed in alcohol and powdered, and sublimed sulphur, each 90 grains; powdered fennel, powdered star anise, and powdered cream of tartar, each forty-five grains; powdered licorice, 120 grains; powdered sugar, 375 grains. Of this a dessertspoonful or a soupspoonful may be taken every evening in half a glass of water.

If there are disorders of the heart, the following prescription is recommended by M. Huchard: Powdered digitalis leaves, squill, and scammony, each seventy-five grains; syrup of gum, a sufficient quantity. This is to be divided into a hundred pills, of which from two to five may be given daily. If there is congestion of the liver, the following capsules will be found more energetic as laxatives: Potassium sulphate, cream of tartar, and potassium nitrate, each ninety grains; powdered digitalis leaves, fifteen grains; to be divided into twenty capsules, of which one or two may be taken daily.

The gastralgia of the menopause does not differ in its treatment from gastralgia under other circumstances.

As regards the administration of iron and arsenic, how should the first of these be administered? If there is reason to fear digestive derangements, by combining its use with that of hydrochloric acid. The preparation of iron is to be taken in the course of a meal, and that of the hydrochloric acid at the

termination of the meal. If there is want of appetite, the iron is to be associated with a bitter tonic; about a fifth of a grain each of iron protoxide and powdered calumba may be given in a capsule. Therapeutists are somewhat at variance in regard to the choice of preparations of iron. The protoxalate, in daily amounts of from a tifth to a quarter of a grain, is to be recommended on account of its solubility and the rapidity with which it is abscribed. It is an eligible preparation of iron, and may be taken before each of the two principal meals. Its use should be begun in small doses, which may be increased gradually. In gastralgic chlorosis we may have recurrence to iron and potassium tartrate. Here are two good prescriptions, the first of which is rather indicated by gastralgic chlorosis, and the second if there is constipation with absence of fever: 1. Iron and potassium tartrate, 150 grains; extract of gentian, 120 grains; extract of nux vomica and extract of opium, each 4 grains. This is to be divided into a hundred pills, two to be taken before each meal. 2. Extract of nux vomica, 8 grains; extract of cinchona, extract of gentian, extract of rhubarb, and iron and potassium tartrate, each 75 grains; oil of anise, 5 drops; glycerin, a sufficient quantity. This is to be divided into a hundred pills, two to be taken at the beginning of each meal.

Arsenic increases the production of red globules. Moreover, it stimulates nutrition, so that it is particularly applicable in the very pronounced forms of anamia. It should therefore, as Luzet has pointed out, be considered not as a substitute for iron, but as an adjuvant. For this reason it is indicated in the chlorosis of the menopause, in the form of arsenical mineral water. We may give the waters of La Bourboule, Plombières, and Mont-Dore, Fowler's solution and Pearson's solution, or the following pills: Sodium arsenate, a grain and a half; glycerin, a sufficient quantity; extract of gentian and extract of cinchona, each 150 grains. To be divided into a hundred pills, of which two may be taken before each of the principal meals. The remedy may be used in the form of powder, combined with iron and bitters, as in Elliot's arsenio-ferrated capsules, each of which contains 0.0015 of a grain of arsenious acid, eight tenths of a grain of aloes, one third of a grain of powdered nux vomica, and a grain and a half of reduced iron-Two of these may be given in the course of twenty-four hours. The arsenical treatment should be discontinued at the end of a month or six weeks, but may be resumed subsequently after a long period of abstention.

With the restoration of the nutrition, any nervous derangement that may have been present will doubtless have been allow viated. Nevertheless, we may have to give special attention to sleeplessness and nervous irritability; for this bromides, especially sodium bromide, are appropriate. If there are phenomena of depression or of a neurasthenic condition, recourse may be had to phosphorus, in the first place, and subsequently to the phosphides. In England, where the use of phosphorus is in greater vogue than in France, Elliot advises beginning with pills each of which contains 0.008 of a grain of phosphorus and 0 15 of a grain of extract of nux vomica, one daily. Later on he prescribes zinc phosphide in the form of pills each containing from 0.30 to 0.45 of a grain of phosphide and 0.15 of a grain of nux vomica, one to be given daily. Finally, there is the resort to hypodermic injections of artificial serum and even of the testicular extract according to Brown-Séquard's method. Undoubtedly the organic extracts will not cure the accidents of the menopause, but it is quite certain that they will contribute to allay its nervous derangements by improving the nutrition. They may usefully precede or succeed the physiological action of hygienic and medicinal measures.

Luke, the Christian Physician of Antioch.—In the December number of the Glasgow Medical Journal there is the

following translation from Professor A. Harnack's Medicinisches aus der ältesten Kirchengeschichte, Leipsic, 1892:

In the Apostle Paul's Epistle to the Colossians (iv, 14) we read: "Luke, the beloved physician, greets you." In the epistle to Philemon (verse 24), written from Rome at the same time, the Apostle calls him his "fellow-laborer"; and in the last writing of Paul's which we possess he says: "Only Luke is with me" (2 Tim. iv, 11).

Luke, the first physician whom we know to have been a Christian, took a prominent part as Paul's "fellow-laborer" in the spread of the Gospel. Church tradition ascribes to him the third Gospel and the Acts of the Apostles, and much may be alleged in favor of this report. Both these books, which form a considerable part of the New Testament, have undoubtedly been written by a highly-cultured Greek, by one who worked with the greatest accuracy as regards the sources from which he derived his information, who thoroughly understood the rules of the science of history, and who wrote in an excellent style. There are also to be found in both works passages which would seem, both from the interest and the knowledge which they display as regards medicine, to point to a physician as their author; \* indeed, it has even been asserted that the preface to the third Gospel is formed after the pattern of the preface to the Materia Medica of Dioscorides.+ It is certain, at any rate, that in no other Gospel is the activity of Jesus as the healer both of soul and body so earnestly brought into prominence and so lovingly described as in the third Gospel. The Acts of the Apostles also concludes with an address by Paul, in which, on the basis of an Old Testament quotation, God is spoken of as the physician who has abandoned the Jews and exercised his healing power exclusively on the heathen."

According to a tradition reaching back to the second century, Luke took part in the composition of yet another of the New Testament Books—viz., the Epistle to the Hebrews. In recent times De'itzsch has come forward to support this idea. He writes: | "That Luke was by profession a physician is strikingly in keeping with the construction of the epistle; for this epistic contains, so to speak, an anatomical (iv, 12), a dietetic (v, 12-14), and a therapeutic passage (xii, 12)." A striking idea, quite like those of the late Leipsic scholar, but of no value whatever as a proof! That Luke was the author of the Epistle to the Hebrews is merely an unauthenticated tradition, having its origin in the difficulties of the subject and the speculations of the learned.

Reasons have also been brought forward, which are worthy

‡ It must also have been noticed that the third evangelist has endeavored to draw a distinct line between the process of exoresing and the curing of "natural" diseases, both as regards their description and the methods used in curing them. See Campbell, Critical Studies in St. Luke's Gospel, Edinburgh, 1891 (known to me only through J. Weiss, Theol. Lit.-Ztg., 1892, No. 3).

<sup>\*</sup> Eusebius says in his Church History, in, 4: "Luke, a scientific physician, bequeathed to us two books in demonstration of the science of soul healing which he had learned from the apostles."

<sup>†</sup> Lagacale, Psalterium inxta Hebr. Hieron, p. 165; compare also Mittheil. III, S. 355. [The following is a translation of the first sentence referred to. Dioscoides is assigned to the first or second century A. D.: "Following many others, including not merely ancient, but recent authors also, who have written concerning the prepuration of medicines, and their powers, and their use, we also, O dearest Areus, will try to show to thee that this matter has been taken up by us after due consideration and with no small amount of study; because some of them have not thoroughly elucidated the subject, and others of them have treated it merely historically."]

<sup>\*</sup> Acts of the Apostles, xxviii, 26-28. The two following verses contain only an appended historical notice.

Comment. 2 Hebraerbrief, S. 705.

of consideration, against the idea of his being the author of the Gospel and the Acts of the Apostles. The fact, however, of his being that companion of Paul who wrote the description of the voyage from Casarea to Putcoli and the shipwreck (Acts of the Apostles, xxvii et eeq.) is beyond dispute. The accuracy and trustworthiness of the description are marvelous. Those who have studied the naval affairs of the ancients consider that in the whole range of antiquity we hardly possess another account so rich in respect of acuteness of observation and clearness of statement regarding nautical matters as this account by the physician Luke.

If Luke be the author of the third Gospel, then we have among the four evangelists, according to report, not only a "theologian," John, who bears this title of honor, but also a "physician"; Mark, as the interpreter of Peter, would be the "philologist"; and the publican Matthew would require to see if he could find a place among the "lawyers." The four evangelists have been compared to every imaginable thing in the world that is fourfold and forms a universitus-to the four quarters of the globe, the four winds, the four cherubim, etc. I know not whether in these comparisons, which were at one time taken quite seriously, any one hit upon the four faculties, but I should be astonished if such were not the case. We do not think much of these matters now, and least of all of the union of the four faculties, which has become somewhat loosened and is in general not so likely to occur to the mind readily nowadays.

It rests on good authority that Luke came from Antioch and was a member of the earliest of the Gentile Christian Churches.\*
Anything further, however, that tradition has to tell of him does not appear till later on, and is not authentic; he is said to have labored in Achaia and Bootia, in Dalmatia, Gaul, Italy, Macedonia, in Alexandria also, and so on. Some give an account of a martyrdom which he suffered in Thebes in Bootia; others say Petrea or Ephesus. Out of the multiplicity of legends tlet us give prominence to the pleasing one, that, on the grave of the saint in Thebes, there rained down pastilles or biscuits endued with healing power, and in this way the forgotten grave was discovered—probably a Bootian local report got up by a speculative priest, who brought as an offering some small cakes in order to procure for his people a sacred shrine, and gain reputation and money for his church.

Not until very late-viz., in the sixth century !-- appeared the information that Luke was not only a physician, but also a painter; but, as is so often the case, the later false legend nearly supplanted the ancient true tradition. The painter Luke soon eclipsed the homely physician. Nowadays Luke is recognized throughout the whole Eastern Church principally as a painter. He became a painter because people wished to have "genuine" pictures of the Virgin Mary, and Luke was the evangelist who had given the most exact description of the mother of God. The tradition that he had been a physician was not, however, at that time intentionally suppressed. True, the heretic Marcion, a celebrated man, though without followers, tried to do this as early as the second century. Marcion would recognize no physician among the apostolic heroes, because in his overflowing Christian enthusiasm he held it as unchristian to busy one's self about the human body. Thus in

Galvanization of the Brain .- Dr. Hobart Amory Hare, of Philadelphia, professor of therapeutics in Jefferson Medical College and editor of the Therapeutic Gazette, contributes to the December number of that journal an article entitled, Is there such a thing as Galvanizing the Brain? He begins by referring to a paper that had been read before the section in nenrology of the First Pan-American Medical Congress, on the treatment of the meth-apoplectic state, in which the author had maintained that marked improvement in the paralysis followed the application of galvanism to the head, one pole being placed on the occiput and the other on the forehead. The idea was, says Dr. Hare, that by this means the current passed from pole to pole through the substance of the brain and so modified its nutrition that the apoplectic injury was modified favorably. He then refers to the fact that in the discussion which followed he had emphatically expressed the belief that the current never passed through the brain under such circumstances, but by the path of least resistance-namely, through the scalp from pole to pole. While some of those present had agreed with him, the majority had felt convinced that the current did pass through the brain substance, and instances have been cited in which undoubted improvement in motility had followed this method of treatment, and in which marked symptoms had been produced in healthy persons by the application of the poles to the two temples. Referring to the general recognition of the fact that electricity always flows in the direction of least resistance, Dr. Hare relates the following experiment: The positive pole of a battery was applied to the occiput of a large dog and the negative to its forehead and a milliampèremeter placed in the circuit. It registered 5.75 milliampères, and the dog was trephined. While the milliampèremeter was used in the circuit a needle thoroughly insulated except at its tip, and connected with one of the poles, was inserted into the substance of the brain. The milliampèremeter now registered 3.75 milliampères. In other words, says Dr. Hare, the resistance to the current when one of the poles was bare metal and in the middle of the brain was greater when the current had to pass through a wet sponge, bone, membranes, and the scalp than when it had to pass from pole to pole by the scalp. If this was the case, he asks, how much greater must the resistance be when the current has to pass through both sides of the skull instead of only one side, as in the experiment? If the current passed through and through, the subject would be thrown into a convulsion by excitation of the motor cortex every time the current was made or broken, and any one, continues Dr. Hare, who has applied the feeblest test to this motor area will appreciate the fact that very powerful motor impulses are excited by this means. The author does not deny that benefit follows the

the Epistle to the Colossians he struck out the words "the beloved physician" standing beside the name of Luke. But this Christianity, in opposition to Nature, which was a revisal even of the old records, was rejected by the Church at large; Luke continued to be to her "the beloved physician," and, as such, the living token at the same time that Christianity and medical science can well be combined. Even in the history of the Church, however, there have been times when all natural science and medicine were almost condemned as profane learning. At such times it was of no little value for her to remember that in the New Testament there appears a "beloved physician," and that he is the historian of the Virgin Mary and of the Lord, of Peter and of Paul. Thus the physician Luke has carried on, even after his death, a quiet but powerful mission. He has protected in the Church his science of healing, and triumphantly averted from the Catholic Church the final consequences of a Christianity opposed to Nature.

therapeutical application of galvanism to the head, but his object is to point out that the benefit must be obtained indirectly and not by the direct action of the current on the cranial con-

Ethyl Bromide as a General Anæsthetic.—The December number of the Medical Reporter, published in Calcutta, contains an abstract of an article contributed to the September number of the Revue de chirurgie by Hartmann and Bourbon, who have come to the following conclusions from an extensive experience in the administration of ethyl bromide as a general anasthetic: It is very important to use the pure drug, and particularly to distinguish between ethyl bromide and ethylene bromide. The use of ethylene bromide is not free from danger, and the bad effects often caused by it have been unjustly attributed to ethyl bromide. When properly administered, ethyl bromide is a very convenient, rapid, and safe anæsthetic. The patient recovers very speedily and does not suffer from any unpleasant feeling. As it causes cephalic congestion, it should not be given while the patient is sitting; and as it can not be administered for a long time with safety, it is not to be used in prolonged operations; in such cases it may be used at first and the anæsthesia continued with the use of chloroform. This method has the advantage of shortening the period necessary for rendering the patient insensible, but does not preclude the possibility of syncope. Ethyl bromide causes an unpleasant odor of the breath for two days after its inhalation, but this is not usually perceived by the patient himself.

Lucas-Championniere's Antiseptic Powder.—The Union médicale for December 30th gives the formulæ of a number of preparations of iodoform mentioned by M. Terrier in his course on operations and dressings. Among them is that of a powder attributed to Lucas-Championnière, consisting of equal parts of iodoform, powdered benzoin, powdered cinchona, and carbonate of magnesium, and a little oil of eucalyptus. It is said that in this mixture the odor of iodoform is masked.

Pseudo-insufficiency of the Aorta. -- At a recent meeting of the Genellschaft tür innere Medicin, of Berlin, reported in the Mercredi médical for December 21, 1893, Dr. Fürbringer stated that several years ago he had attended a patient who had presented all the symptoms of aortic insufficiency, except the souffle. At the autopsy degeneration of the aortic valves was found. Since that time Dr. Fürbringer had met with several identical cases out of the three hundred cases of aortic insufficiency which he had observed; but in another group he had found cases where the souffle was intermittent and disappeared for a time. This disappearance was attributed to the condition of the blood pressure, but it must be understood that this disappearance of the souffle sometimes persisted when the patient was at rest. Dr. Leyden had observed a certain number of cases of acute rheumatism followed by signs of aortic insufficiency, but with a systolic souffle. Dr. Litten had never observed any patient with aortic insufficiency, verified at the autopsy, without finding that during life he had had the souffle at the base of the heart. Relative aortic insufficiency, where the dilatation of the valvular opening was not in proportion to the degree of constriction, was to be distinguished from pseudoinsufficiency.

The Use of Colchicum in the Chronic Rheumatism of Children.—In the Revue générale de clinique et de thérapeutique for December 27, 1893, M. Jules Simon is credited with the opinion that this remedy is the most efficacious. He prefers it to iodide of potassium and follows its use by that of tonics, such as arsenic, hæmoglobin, and phosphates, together with dieting. The following method of administration is advised:

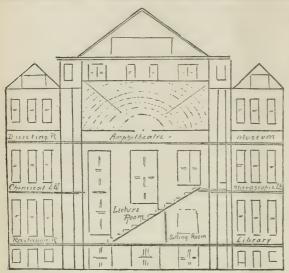

An hour before dinner, every day, take ten drops of tincture of colchicum and continue this for eight days, when it is best to allow a week to pass before resuming the treatment, which is then to be continued until recovery is completed. Colchicum rapidly diminishes the swelling of the joints, but does not affect the general condition so quickly. The use of it can be alternated with that of iodides, so that the treatment then becomes a mixed one.

A Simple Stamp of Sterilization.—The Revue générale de médecine, de chirurgie et d'obstétrique publishes an abstract of an article by Dr. H. Hochenegg, which appeared in the Wiener klinische Wochenschrift, 1893, No. 23. The author begins by asking how one may satisfy himself that articles of dressing have been sterilized. He makes use of a vellowishbrown coloring matter which has the property of becoming bright red on exposure to the temperature of boiling water. This coloring matter is applied to certain parts of the articles that are to be sterilized. If the sterilization has been done effectively and satisfactorily, spots that were yellow have become red, and all mistakes are avoided. The coloring matter consists of a mixture of a hundred and fifty parts of the solution of aluminum acetate of the Austrian Pharmacopæia, a hundred and fifty parts of fountain water, and five parts of a twenty-one-per-cent. paste of alizarine. The mixture is to be shaken before it is used, and with it one of the surfaces of the article is to be painted. In the cases of compresses and the like the date of the sterilization is to be written in one corner with the coloring matter. The red color of the date bears witness that the sterilization has been accomplished efficiently. This process is at once very simple, very practical, and cheap.

The Medicinal Treatment of Typhlitis.—The Revue générale de clinique et de thérapeutique for December 6th gives a summary of M. Grasset's views on this subject. The therapeutical indication, he says, varies accordingly as there is an actual acute inflammatory attack, or as the case is one of recurrent typhlitis between the attacks, or as there is typhlitis with persistent cæcal engorgement. In the last named case medicinal treatment usually fails, and an appeal to the knife becomes a necessity. In the case of a recent typhlitis with acute exacerbations the physician may treat the appendicular colic, combating the pain with warm baths, evacuating the intestinal contents, and, if possible, resolving the inflammation. M. Grasset fulfills these various indications as follows: 1. He gives a full warm bath of from half an hour to an hour in duration. 2. Every hour the patient is to take a teaspoonful of a purgative potion, consisting of one part each of castor oil and oil of sweet almonds and two parts of syrup of lemon, until a copious evacuation of the bowels has been produced. 3. The iliac region is to be anointed with an ointment consisting of mercurial ointment and belladonna, and this is to be followed by the application of a large. hot, thin poultice of linseed meal. In very stubborn cases M. Grasset adds to the purgative potion a drop of croton oil. In cases of recurrent typhlitis the treatment during the intervals consists in preventing overloading of the intestinal canal and in the use of antisepsis, revulsives, and resolvents to the seat of inflammation. For this purpose he advises: 1. A diet that leaves little residue. 2. Every week the application of the actual cautery to the painful and infiltrated region; also every day, or as often as may be necessary, frictions with an ointment containing belladonna. 3. To overcome constipation, at bedtime a laxative pill, consisting of one sixth of a grain each of powdered belladonna, extract of belladonna, and podophyllin. 4. The insurance of intestinal antisepsis by taking before and after each meal a capsule containing seven or eight grains of benzo-

rangement of the building are shown in cuts, and of these we | with grindelia as a topical application, but he quoted M. Bardet the first floor.

The Therapeutical Uses of Grindelia Robusta. -- At a recent meeting of the Societé de medecine et de chirurgie pratiques, the proceedings of which are reported in the Mercredi médical for December 7th, M. Jasiewicz remarked that Grindella robusta, long employed in the United States, had of late years begun to be made use of in France. The entire plant was employed, but the active part was a resin obtained especially from the flower heads and the involucre. The preparations in use were the fluid extract (dose, from seven to forty-five grains), a tincture (dose, tifteen to forty drops), and an alcoholic extract (dose, three pills daily, each containing from a grain and a half to two grains). All these preparations, he said, were readily taken by patients. In view of the slight toxicity of the drug it might in case of need be given in pretty large doses, but care should be taken to give it in divided doses, because according to Bardet, large quantities taken at one time might prove fatal. As for its physiological action, grindelia, according to Bartholow, one of the authors who had most thoroughly studied it, caused a slight sensation of heat in the stomach, retarded the pulse and respiration, dilated the pupils, and gave rise to sleep. It had a sharp, somewhat acrid taste. Although it was not very poisonous, from a hundred to a hundred and twenty grains of the

Richardson, the widow of the late Dr. T. G. Richardson, the fluid extract was capable of killing a rabbit after producing of anatomy and clinical surgery. The plans and general ar- opinion had been confirmed in practice, grindelia was indicated

> in all the respiratory neuroses, such as asthma (and especially spasmodic asthma), whooping-cough, nervous cough, and hay fever and emphysema. The plant acted favorably also in acute bronchitis, but its employment had to be continued for a certain length of time. In chronic bronchitis the results were less satisfactory. To tell the truth, in whooping-cough antipyrine appeared to have sedative powers superior to those of grindelia. The latter, however, could be given for a greater length of time without danger, and this was a very great advantage in a disease the treatment of which was always prolonged, of whatever sort it might be. Indeed, although grindelia diminished the violence of the paroxysm-, it did not appreciably shorten the duration of the disease, which really was not a respiratory neurosis, but a distinctly infectious disease, against which it was necessary to use tonics and antiseptics along with antispasmodics. But in asthma the action of grindelia was much more efficient. It allayed the dyspnœa and, so long as its use was continued, staved off the occurrence of the paroxysms, but could not prevent their ulthnate return. So far as this last-named purpose was concerned, potassium iodide was the only drug indicated. The author had had no experience

here reproduce two, for which we are indebted to Professor as regarding its use in elytritis, genito-urinary catarrhs, and Souchon. They show the building in section and the plan of burns; also M. Bocquillon as having pointed out its utility in allaying the irritation of skin diseases.

# LECTURES ON THE DIAGNOSIS OF ABDOMINAL TUMORS.\*\*

BY WILLIAM OSLER, M. D., PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY. LECTURE I.—TUMORS OF THE STOMACH.

Gentlemen: I propose in the following course to bring before you the experience gleaned during a period of twelve months in the cases of abdominal tumor which have come before me for diagnosis. I have not included the cases admitted under the care of Dr. Thayer (my first assistant) during my absence in July and August, unless I had previously or have afterward seen them. The condition has been dictated at the time of examination, the diagnosis made, when possible, and the subsequent history of the cases has been carefully followed. I have not included in the list instances of ascites, appendicitis, or simple enlargement of the liver or spleen; only cases in which a definite tumor existed in connection with one or other of

In the diagnosis of abdominal tumors Bishop Butler's maxim that "probability is the rule of life" is particularly true, and the cocksureness of the clinical physician, who formerly had to dread only the mortifying disclosures of the post-mortem room, is now wisely tempered when the surgeon can so promptly and safely decide upon the nature of an obscure case.

the abdominal organs. We shall take up the cases in the

following order: stomach, of which there were twenty-

four, liver and appendages, intestines and peritonæum,

renal, and miscellaneous.

With the methods of examination of the stomach you are all familiar, having frequently seen them applied; and as elaborate details are available both in the text-books on physical diagnosis, and more fully in the recent special works on diseases of the stomach by Ewald,† Boas,‡ Bouveret,# Debove, and Rémond, I shall proceed at once to the consideration of the subject in hand.

Tumors of the stomach are formed (1) by the organ itself in a condition of abnormal dilatation or contraction; (2) by nodular or massive outgrowths of its walls.

I. The Tumor formed by a Dilated Stomach.—
There were thirteen cases of dilated stomach in the series, in ten of which the organ itself formed a prominent tumor visible on inspection. These will form the subject of the present lecture. In all of the cases the existence of a nodular pyloric tumor was also determined. In another case, not considered here, the dilatation of the stomach was caused by the pressure on the duodenum of a tumor of the

colon. I will first read to you the histories of the cases, sometimes with the comments dictated at the time of examination, and then make some general remarks on the diagnosis of dilated stomach. Though the condition is common, I am surprised that general practitioners so frequently overlook its presence, owing in large measure to the transgression of one of the primary rules of diagnosis, namely, to carefully and systematically go through the routine of inspection, palpation, percussion, and inflation.

Case I. Tumor caused by Dilated Stomach; Nodular Tumor in Right Epigastriam; Wares of Peristalsis.—George A., aged thirty-nine, admitted September 1st, complaining of pain in the abdomen and vomiting. Patient is a tailor by occupation, and has used alcohol to excess. Present illness began last Christmas with symptoms of dyspepsia, occasional vomiting, eructations, and pain in the region of the navel. The pain was much worse after enting and was described as of a gnawing character. The food very often turned sour. Has never vomited any blood. Lately the attacks of vomiting have come on at longer intervals and large quantities of brownish, foul-smelling material have been ejected.

Present Condition.—Patient is a medium-sized man, much emaciated, particularly in the trunk and extremities; there are no glandular enlargements. The tongue is thickly furred. The abdomen is flat, somewhat scaphoid, but presents a slight prominence above and to the left of the navel. At intervals of a minute or two there appears in the epigastrium and apper umbili-

Fig. 1.—From a photograph by Dr. Hewetson, showing undulatory waves of peristalsis in Case I. The crosses are placed on the three prominent waves. The letter f indicates the depression on the lesser curve.

cal region a prominent tumor, the longest diameter transverse, and having somewhat the shape of the stomach. The chief prominence is in the left hypochondrium, and the greater curve emerges beneath the costal margin in the left nipple line, passes obliquely downward to about two inches below the level

<sup>|</sup> Traité des maladies de l'estomac, Paris.

of the navel, and then turns upward and to the right, reaching nearly to the ribs. The lesser curve, not so distinct passes two inches from the ensitorm cartilage. During the prominence of the tumor waves of contraction pass from left to right and there is sometimes a well-marked depression separating the prominent masses to the left and right of the middle line. During the periods of contraction the masses are firm and resistant; in the intervals they almost completely disappear and the abdomen in these regions is quite soft. In the right parasternal line, just below the edge of the liver, is a nodular tumor.

Fig. 1 is from a photograph taken during the passage of the waves of contraction, three of which are plainly to be seen at the situations marked with the crosses. The letter f is placed in the depression separating the stomach into right and left. After several attacks of vomiting, and after having the stomach thoroughly washed out, the distention was very much less marked, and the peristaltic movements were less frequent. The nodular tumor mass was then felt to be very much more in the middle line. For a week or ten days before his death this patient bad tetany, which is not a very uncommon event in dilatation of the stomach. Death occurred September 26th.

The autopsy showed at the pyloric extremity of the stomach a crater-like tumor mass eight by seven centimetres, the margins thick, elevated, and indurated. Externally there was great thickening about the pylorus, with numerous nodules on the peritonsum. At the pylorus the tumor was massed about the orifice, through which, however, the little finger could pass.

Fig. 2 Cacu on each pytorus, showing the call tation of the scomach as it appeared at autopsy — From a photograph by Dr. Hewetson

The coats of the stomach were enormously thickened. Fig. 2, from a photograph taken on the post-mortem table, shows well the dilatation of the stomach.

CASE II. Dilated Stomach, forming a Prominent Tamor; Ill-defined Flattened Moss in Right Umbilical Region.—John L., aged fifty-eight years, seen with Dr. Bryson Wood, September 18th, complaining of indigestion and loss of weight. The patient is a tail, large-framed man, who has lived a life of un-

usual energy and activity, and prior to 1875 had been a hard drinker.

His mother died of some stomach trouble, the precise nature of which he does not know. With this exception, his family history is good. He has always had to be a little careful about eating, but until within the past six months has had good health. The present illness began with dyspeptic symptoms, eructations of gas, feelings of distress a few hours after eating, and occasional vomiting. The chief discomfort was at night, five or six hours after the last meal. Lately these features have increased very much; be has not been able to take solid tood; the eructations of gas have become very marked, and he has had at intervals vomiting of large quantities of liquid and undigested food. He has lost rapidly in weight and has fallen from a hundred and ninety-five to a hundred and forty-two pounds.

The condition on examination was as follows: Large-framed man, not cachectic-looking, moderately emaciated. The tongue has a light white fur.

The abdomen is below the level of the costal margin. In the upper zone, occupying the left epigastric, the left umbilical, and the left hypochondriac regions, there is an irregular swelling which at intervals shows waves of peristalsis and assumes a shape suggestive of a distended stomach. A lesser curvature can be distinctly seen three fingerbreadths from the ensiform cartilage; a greater curvature about two inches below the level of the navel. The most marked prominence is just beneath the left costal margin. To the right the outline of the swelling extends beyond the nipple line. The contrast between the upper

and lower abdominal zones is very striking and the diagnosis of the condition could be made at a glance, as the organ hardened when the waves of peristalsis passed over it.

On palpation, the abdomen was everywhere soft and there was no tenderness. During contraction the stomach was firm and resistant. There was no nodular tumor to be felt, although between the navel and the right costal margin there was a sense of increased resistance, particularly beneath the ribs. The area of liver dullness was diminished. There was no enlargement of the superficial glands.

The patient was ordered to lines in Case II.
have the stomach washed out
every morning, and to take a diet of milk and egg-white.

Fig. 3. Showing the stomach outlines in Case II.

October 17th.—Patient was seen again to-day with Dr. Salzer, partly with a view of determining the advisability of a Loreta's operation. Since the last note the patient has improved considerably under the daily use of the stomach tube, and he has been able to take Leube's beef extract, meat balls, and small quantities of milk without discomfort. He has not, however, gained in weight; still looks very haggard and emaciated, and says he at times feels very queer in his head, as if he would go crazy.

The abdomen is a little full in the upper zone and every few minutes the distinct outline of the stomach can be plainly seen, forming a tumor of unusual prominence. The stomach tympany can be obtained as high as the fifth interspace in the parasternal line.

On palpation, there is no thickening or nodular mass to be

felt in the epigastric region, nor on the deepest inspiration can any mass be felt beneath the left costal margin. Just below the limit of the stomach and to the right of the navel there is an ill defined flattened mass which does not, however, feel like a thickened pylorus, nor is it likely that the pylorus could be felt in this situation with the stomach tympany and the outline of the stomach passing, as it does to day, with such distinctness beneath the right costal margin. It seems more probable that the pylorus is covered by the distended organ.

October 26th.—Subsequent to my last visit the patient was transferred by Dr. Salzer to the care of Dr. Simon, who tells me that uremic symptoms developed about the 23d and the patient died comatose on the 25th. There was no autopsy.

Case III. Dilatation of the Stomach; Tumors in Epigustric and Right Hypochondriac Regions.—A. P., aged forty-seven years, seen October 19th with Dr. Jarrett, of Towson, complaining of indigestion and stomach trouble. His personal and family history are excellent, though he states that one brother died of a tumor in the abdomen. For the past six months he has been in failing health and has had distress after eating, usually within half an hour, sometimes as soon as ten minutes. The vomitus consists of the food be has taken, never any blood. He has never vomited any very large quantities. The pain is marked after eating and becomes more severe until the contents of the stomach are ejected. On several occasions he has passed blood in the stools, but he thinks this comes from hæmorrhoids which he has had for many years.

The patient is a very well built man, looks thin, but is a little sallow, searcely cachectic. Tongue is red, clean, and indented.

Abdomen.—Wallsthin. Occupying the left epigastric region there is a large projection which varies in shape and in prominence. Definite peristalsis is to be seen, but the waves do not pass beyond the middle line. This bulging during peristalsis occupies the left epigastric and the upper right quadrant of the umbilical regions.

On palpation, the abdomen is everywhere soft, very resistant just below the ensiform cartilage and over the prominence

Fig. 4.—Showing the position of the tumor masses in Case III.

above noted. In the latter the resistance varies with the presence or absence of the peristaltic waves. Immediately below the ensiform cartilage there is a definite ridge-like swelling which is superficial, very tender, and does not extend entirely across the space between the costal margins. It has a boardy hardness. On drawing a deep breath the fingers can be placed directly above it and it descends about an inch. In the left lumbar region, just below the tenth rib and the adjacent costal margin, there is to be felt a firm mass, extending seven centimetres in a vertical direction. Anteriorly in reality it can be felt within the right epigastric region, and

outward it extends to nearly the mid-axillary line. On deep inspiration it descends and gives one somewhat the impression of a rounded body, and on bimanual palpation it is not very movable.

The edge of the spleen is not palpable; neither kidney can be felt; the edge of the liver is not palpable; nor does there appear to be any definite enlargement of the organ. On inflating the stomach the prominence in the epigastric and umbilical

regions becomes very marked and its lower curve extends to a little below the navel. The upper limit of stomach tympany is just at the sixth rib in the nipple line. There are no glandular enlargements. The patient became gradually worse and died about Christmas time.

Case IV. Dilated Stomach, forming a Visible Tumor; an Oblong Mass in the Right Epigastric and Umbilical Regions.—
Annie D., aged forty-eight years, Bohemian, admitted October 1st, complaining of swelling in the abdomen, pain in the back, and vomiting.

She knows of no hereditary disease in her family. Her husband died of tuberculosis,

Patient was always strong and well; she has had three children. Her present trouble began eight months ago with pain of a dull, aching character in the stomach, and dyspepsia, but until recently she has had no vomiting, and has kept about and at work up to a week ago, when she began to vomit. Prior to this she noticed that the abdomen was swollen. The vomiting has been chiefly after taking food, and she has not brought up any large quantities.

Present Condition.—Patient is thin, but the emaciation is not extreme. The lips and nuccous membranes are of a fairly good color. Tongue is slightly furred with a white coating, Pulse regular; temperature normal; superficial glands not enlarged.

The abdomen is prominent, particularly in the umbilical and left hypochondriac regions. Under observation there occur in these parts undulatory waves of peristalsis, and the outlines of the stomach become unusually distinct, the greater curvature reaching fully three inches below the level of the navel, the lesser curvature just above this point. As the waves

of contraction pass there is a vertical constriction just to the left of the middle line. The peristalsis comes on spontaneously, and any stimulus, such as flipping with a towel or even palpation, at once excites it. On palpation, except during the time of the contraction referred to, the abdomen is everywhere soft. Just above and to the right of the navel there is to be felt an oblong mass, which takes a direction upward and outward toward the costal margin. It is oblong, slightly movable, firm, smooth, and not painful.

On October 3d a test breakfast was given at 8 a.m. At nine o'clock the stomach tube was introduced and about a quart and a half of very sour-

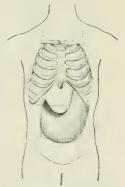

Fig. 5.—Showing the position of the tumor and the outlines of the stomach in Case IV.

smelling, brownish material removed. During the passage of the stomach pump the patient vomited, and she felt very faint. The examination for free hydrochloric acid was negative.

The patient left the hospital on October 14th in much the same condition, and has not been heard of since.

CASE V. Remarkably Marable Tumor of Pylorus; Diloted Stomach; Gastro-enterostomy.—Mary M., aged fifty-eight years, colored, admitted on October 26th, complaining of pain in the abdomen and vomiting.

She has been a healthy woman, married twelve years; has had six children and four miscarriages. She has always had very good health up to the onset of present illness, which began in June with burning feelings in the chest and pain after eat-

ing, sometimes vomiting. These symptoms have continued with variations. At times she would be better, and then she would have spells of belching and vomiting. She had often vomited large quantities of liquid. She makes no complaint except of the stomach symptoms. Lately she has been very constipated.

Abdomen.-The walls are very loose, flabby, thrown into many folds. In the right hypochondriac and right epigastric regions there is a marked rounded prominence, which below extends to within two centimetres of the navel, and reaches nearly to the middle line. It descends slightly with inspiration. On palpation, this proves to be a solid mass, which can be grasped and is freely movable. It is irregular, rounded, not reniform, but is smooth at its upper and right borders, more irregular below and to the left, but a definite hilum is not to be felt. To the touch there is conveyed a sense of firm yet elastic resistance, such as is given by a solid organ. On prolonged palpation no gas is felt passing through it. It is extraordinarily mobile, and can be pushed into the epigastric region far over into the right hypochondriac region, and below into the right lumbar and umbilical regions to a level with the line of the anterior superior spines. On firm pressure, the lower margin can even be forced into the iliac region. The diagram, which was made with great care, illustrates the various positions which the mass can be made to assume. It can also be pushed into

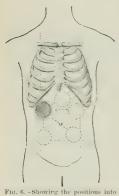

Fig. 6. -Showing the positions into which the tumor could be placed in Case V.

the right hypochondriac region, so as to be covered almost completely by the ribs, and in subsequent examinations this was not infrequently the situation in which it was found, and from which it could only be dislocated by the deepest inspiration or by deep pressure in the renal region. The mass is not tender even on firm pressure. There is dullness over it, but not complete flatness. The patient notices that the mass changes in position as she moves about, and when she sits up it moves far down into the abdomen, while when on her back it is frequently beneath the right ribs. When this mass is out from beneath the right costal margin the right kidney can not be felt, nor on

the left side, on the deepest inspiration, could the kidney be palpated. Behind there are depressions in the renal regions.

The edge of the liver can not be felt; the area of splenic dullness is not increased; the edge can not be reached even on deep inspiration.

A test breakfast, withdrawn an hour and ten minutes after, gave two hundred cubic centimetres of fluid in the stomach, which contained no free hydrochloric acid. The stomach was inflated with gas, and the outline of the greater curvature reached almost to the navel. When the gas was in the stomach, palpution of the most careful character gave no sensation of any fluid passing through the tumor.

This patient came in with a diagnosis of probable cancer in the stomach, which the history of repeated attacks of vomiting and progressive loss of weight and the existence of a tumor in the abdomen seemed to justify. Extreme mobility is a feature of certain tumors of the pylorus, as in the specimen which I showed at the Philadelphia

Pathological Society of solid tumor of the pylorus, about the size of the mass under consideration, which could be moved readily into either hypochondriac region, and which was sometimes completely under the ribs and out of reach. The autopsy showed it to be a tumor of the pylorus. The possibility of such cases has to be considered in speaking of the nature of the present one. Here the mass is of unusual mobility, and can be passed into the renal region on the right side. It has not a reniform shape, but it has the consistence and the resistance of the kidney. A point very much in favor of its renal character is the mobility downward, and the tumor of this sort which can be pushed up beneath the ribs and also far down to the iliac regions is certainly highly suggestive of floating kidney. Another important fact is that, in a woman with such a lax abdominal wall, no right kidney can be felt. The gastric disturbance and dilatation of the stomach present are both explicable on the view that this tumor mass has compressed the duodenum and caused secondary dilatation. Nor is this, considering the history of so many cases, inconsistent with the view that the tumor mass may be really a kidney. On the other hand, the tumor has not the shape of a kidney, and a distinct hilum can not be felt. No left kidney can be palpated, and it may be that this is an instance of conglomerate kidney, such as was found in Polk's celebrated case.

At any rate, I have suggested to Dr. Halsted that an exploratory laparotomy be made, and if it is found to be a movable kidney, the organ can be stitched into position.

November 4th.—The patient has been better for the past few days. She has had her stomach washed out early in the morning. To-day at ward class a careful examination was again made. The tumor mass was evident just beneath the right costal margin, and it was difficult to displace it from this point by the deepest inspiration; but, on turning on the left side, it readily fell over toward the umbilicus, and had practically the mobility noted before. The stomach was again inflated, and the outlines became remarkably plain. The greater curvature was just about the level of the navel, somewhat above the level previously noted. The peristals was unusually distinct.

5th.—This morning at 10.30 Dr. Halsted operated, making a long vertical incision over the right rectus. When the peritoneum was opened the tumor mass was directly exposed, and found to be a solid growth of the anterior wall and lesser curvature of the stomach in the pyloric region. There were no adhesions: the stomach was much dilated. He at first intended to resect the tumor, but, on examining the retro-peritoneal glands, they were found to be enlarged, and it was thought best to do a gastro-enterostomy. The patient died two days afterward.

Case VI. Tumor in Left Epigastric Region; Dilatation of the Stomach.—In consultation with Dr. Barclay I saw to-day, December 6th, A. B., aged sixty-four years, a German.

Patient had been in failing health for some months, and had had dyspepsia for several years. He, however, kept about and at his work until early in October, when he consulted Dr. Barclay for jaundice, which seems to have been intense and to have come on suddenly, not, however, with much pain and not in a way suggestive of gallstones. He had never had jaundice before, but had one or two attacks of pain resembling that of gallstone colic. On examination, the left lobe of the liver was found to be enlarged and a tumor mass occupied the whole of the epigastric region. It was tender, not fluctuating, and the

doctor regarded it as an enlarged left lobe of the liver. He had moderate fever. After the persistence of these symptoms for some weeks he vomited a quantity of pus, the tumor mass gradually disappeared, and the jaundice became less intense. The gastric symptoms, however, continued and he began at intervals to vomit large quantities of dark-brown material, containing undigested remnants of food. The doctor has washed out the stomach with great relief, but he has gradually failed and has become more ansmic.

Present Condition.—The patient is fairly well nourished; fare is not especially emaciated, and he has not a cachectic look. There is no jaundice. The temperature is normal; pulse about 96, of fairly good volume; tongue is slightly furred.

Abdomen .- Panniculus is well preserved. The upper zone is prominent, particularly in the left hypochondriae region, and at intervals a distinct hemispherical prominence appears below the left costal margin, and waves of peristalsis are seen passing from left to right. The prominence is noticeable as far as the navel, but a definite contour of the stomach is not visible. Midway between the ensiform cartilage and the navel and a little to the left there is a tumor-like prominence which moves with the descent of the diaphragm. On palpation, the abdomen is everywhere soft, quite painless on pressure, and the tumor mass just described is felt as a firm, solid body about five centimetres in vertical extent and about six centimetres in transverse extent. It is entirely to the left of the middle line. It is firm, smooth, not painful, except on very firm pressure, and is not movable. It descends about four centimetres during inspiration. No gurgling is felt in it. Nothing is to be felt to the left of the median line in the pyloric region. Splashing can be readily obtained, and on percussion the stomach tympany extends to a finger's breadth above the navel. The upper limit of the liver dullness in the mamillary line is at the seventh rib, and it does not extend beyond the costal margin. The left lobe of the liver is not palpable; the duliness is at the juncture of the fifth costal cartilage with the sternum, and extends three fingers' breadth. It can be separated from the dullness over the tumor mass in the epigastric region. The spleen is not enlarged. There are no superficial glandular enlargements.

The patient had had a severe attack of vomiting this morning, and his stomach was not nearly so much dilated as usual. The vomited matter which I saw had the usual characters—dark brown, with frothy seum. The urine was somewhat diminished, and he complained very much of thirst.

Two points of interest present themselves in this case, which otherwise seems to have all the characters of ordinary dilatation of the stomach from pyloric obstruction. In the first place, the nature of the attack of severe jaundice with the tumor mass in the epigastric region. From Dr. Barclay's account, there can be no question that the patient vomited a large quantity of pus, and that subsequent to this the tumor disappeared and the jaundice got better. There are two suggestions in this connection: that there was a large carcinoma of the stomach, with suppuration at its base and about the tissues of the gastro hepatic omentum, with compression of the bile ducts. Suppuration does occur at the base of malignant growths, more particularly when they form adhesions with adjacent organs, and I have placed such instances on record; indeed, there may be a considerable collection of pus between the left lobe of the liver and the stomach. The other suggestion is that the jaundice and enlargement of the left lobe of the liver were associated with gallstones and suppuration in the region of the ducts, with discharge into the stomach, and subsequent cicatricial contraction about the pylorus and dilatatio ventriculi. The jaundice, however, would scarcely have disappeared, and this is not a very likely condition. And, lastly, it is interesting to note here the situation of the tumor mass—not at all in the position usually felt in carcinoma of the pylorus, but, as will have been noted in the histories of the other cases, the tumor is extremely variable in position. Though in a somewhat unusual situation, it is quite possible that this really may be a tumor mass causing the stenosis of the pyloric orifice.

Dr. Barclay writes me that this patient died on the 29th of December of exhaustion. The post-mortem showed an enormously distended stomach, which covered the intestines like an apron. The pyloric orifice was surrounded by a large mass of cancer, which so nearly occluded it that only the tip of the finger could enter. The cancer extended also slightly into the duodenum and on the posterior wall of the stomach, which showed extensive ulceration. The left lobe of the liver was shrunken and showed soft, nodular masses breaking down into pus. The mesenteric glands were enlarged and cancerous. The bile passages and gall bladder were normal.

The post mortem does not throw much light upon the early history of this case, the symptoms of which came on apparently with jaundice and enlargement of the left lobe of the liver. The tumor mass proved to be, as was supposed, at the pylorus, though in a somewhat unusual situation—entirely, at the time of my visit, to the left of the middle line.

Case VII. Dilated Stamach: Tumor at the Pyloric Orifice.— October 1st. I saw to day, with Dr. W. B. Perry, Mrs. R., aged about sixty years, complaining of dyspepsia and vomiting. She had been a healthy woman until about a year ago, when she began to have attacks of dyspepsia and occasionally of vomit-

ing. These symptoms have become progressively aggravated and she has within the past three months lost fiesh rapidly. A marked feature in the case has been the vomiting at intervals of very large quantities of a brownish liquid mixed with portions of food.

Patient is a small-framed woman, much emaciated, and looks very feeble. The abdomen is greatly distended, chiefly on the left side and below the level of the navel. The nature of the trouble is at once apparent by the active waves of peristalsis which, as they pass from left to right, bring out with unusual distinctness the contour of the greater and lesser curvatures, the former passer

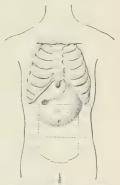

Fig. 7.—The position of the nodule and outlines of the stomach in Case VII.

ing at a level of about three inches above the pubes, and the latter midway between the navel and ensiform cartilage. The organ becomes unusually hard and firm. Far over to the right, just at the border of the epigastric and umbilical regions, there is to be plainly felt an irregular, nodular mass, which is movable and is depressed on inspiration. No gas is felt passing through it, but the position and characters suggest a pyloric cancer. Lavage had been already practiced for some time, but she was in too feeble a condition to expect much from any treatment.

Dr. Perry writes that the patient died on October 4th.

Case VIII. Dilatation of the Stomach, farming a Visible Tumor: Nodular Moss at the Pylorus.—January 10, 1863, Captain —, of Virginia, patient of Dr. R. J. Hicks and Dr. Salzer, came complaining of dyspepsia and discomfort after eating.

The patient has been a healthy man, a free liver, and a late sitter; irregular in his meals. He has not been a chronic dyspeptic, and has only had an occasional attack of indigestion until the onset of the present trouble. From Christmas, 1891, he has been ailing, though able to attend to his business. He has had loss of appetite; no special nausea, and has never vomited any large quantity. After eating, however, particularly an ordinary meal, he has feelings of uneasiness and distress, and rumbling and distention in the upper part of the abdomen. He has never had any severe pain, but a sense of uneasiness when the stomach is full and occasionally a griping pain. Ever since the attack of diarrhoa following the influenza he has had obstinate constipation. There has been persistent loss of weight, from a hundred and ninety to a hundred and forty-five pounds. Though attending to his business, he is at times very weak and feeble, and feels that he has lost a great part of his former vigor.

Present Condition.—Thin, not extremely emaciated, not cachectic; color of mucous membrane good. Abdomen a little below level of costal margin; marked fullness in epigastric and umbilical regions, leaving a definite furrow along right costal margin. During observation distention becomes much more marked, and at intervals the outline of the stomach is unusually distinct. Waves of peristalsis pass actively from left to right, and the lower limit of the stomach is seen to be at least a finger's breadth below the navel. To the right it extends almost to the costal margin opposite the tenth rib. The peristalsis is unusually active, waves passing every few moments, and during their passage the stomach walls become hard. Gas can be heard bubbling through the pylorus.

Palpation.—Everywhere soft; no special resistance except over the stomach itself when in contraction. The pylorus can be felt in the parasternal line at a point midway between the navel and the tip of the tenth costal cartilage. Here is a firm thickening about the size of a large walnut. Though this is a little far out and low for the situation of the pylorus, yet the stomach is a good deal depressed and the whole pyloric ponch lies to the left of the middle line. There is nothing special to be felt along the line of the lesser curvature. There is a little resistance between the costal margin and the navel, which is probably due to the right lobe of the liver. Gas is not felt to bubble through this pyloric mass, nor does it seem to vary in resistance and hardness.

January 22d.—Patient came into the private ward under my care, chiefly to determine whether an operation, which had been suggested by Dr. Salzer, was advisable or not. On admis sion, the stomach was very much in the condition mentioned in the previous note. Ewald's test breakfast, withdrawn an hour after, yielded two hundred and fifty cubic centimetres of a clear, slightly yellow fluid containing partially digested bread. The odor was sour; the tests for free hydrochloric acid were negative.

He had at times a great deal of distress, owing to the active character of the peristaltic movements. He was placed on a diet of milk, beef juice, and egg albumin, small quantities being given every two hours. The stomach was thoroughly emptied night and morning.

Within a few days this treatment made the greatest change in the condition of dilatation; the organ reduced greatly in size, the waves of dilatation were no longer evident, and he felt much more comfortable. The reduction in the dilatation made a very marked change in the tumor mass above mentioned. Instead of a small, nodular body to be felt far over to the right, there was now evident to the right of the parasternal line, in the epigastric region, a large, solid mass of the size of an egg. In spite of the improvement in the local condition, his general strength failed with rapidity, and on the 28th it was thought advisable for him to be removed to his home, where he died early in March.

(To be concluded.)

#### ACUTE PNEUMONIA IN CHILDHOOD.\*

BY THOMAS S. SOUTHWORTH, M. D.,
PATHOLO IST TO THE NURSERY AND CHILD'S HOSPITAL;
ASSISTANT, MEDICAL DEPARTMENT, VANDERBILT CLINIC;
INSTRUCTOR IN DISEASES OF CHILDREN, NEW YORK POLYCLINIC.

It has seemed to me that in an association of this nature it should be the endeavor of the members to present, when practicable, such subjects as shall touch upon the daily labor of the greatest numbers, rather than the curious and exceptional phases of medical experience. It is with this idea that I bring forward to-night the well-known subject of pneumonia in children, in the hope that each one whose general practice brings him into contact with children may contribute something to the discussion which will follow. As it is my aim, as far as possible, to avoid the hackneyed aspects of the subject, I will, without apology, make use of the terms lobar pneumonia and broncho-pneumonia as best expressing to me the essential differences of the two divisions of the subject. With the classical picture of lobar pneumonia-showing microscopically the pulmonary alveoli filled in varying degrees with fibrin, leucocytes, desquamated alveolar epithelium, and red blood-cells, but with an otherwise intact pulmonary framework-you are doubtless all familiar, as also with the four pathological stages of congestion, red hepatization, gray hepatization, and resolution, through which the process passes.

Many of you, I presume, gained the impression from text-books that cases of lobar pneumonia were of extreme rarity under the fifth year. Statistics now show us that about thirty-three per cent. of the pneumonias of even the first two years of infancy show the well-marked clinical course and pathological features of the lobar variety in the adult. These cases can usually with care be readily differentiated from those of broncho-pneumonia, although there are occasional instances over the classification of which the authorities are at variance.

Lobar pneumonia in a large proportion of cases is caused by an oval coccus called the *Micrococcus lanceolatus* (*Diplococcus pneumonia*, pneumococcus of Fraenkel). There are, however, occasional cases in which the clinical story and morphological character of the lesion are similar to those

<sup>\*</sup> Read before the Hospital Graduates' Club, November 23, 1893.

of lobar pneumonia, which are associated not with the Diplococcus lanceolatus, but with other germs, such as the bacillus of Friedländer, pyogenic bacteria, etc.\*

Lobar pneumonia occurs most frequently during the spring months, and attacks by preference strong and previously healthy children, without especial preponderance of either sex. In the typical case the onset is sudden, ushered in most commonly by vomiting and a high temperature, occasionally by partial or general convulsions or a chill. The breathing is so rapid as to attract attention. The respiration has a characteristic rhythm; the quick, anxious inspiration is followed by a distinct pause before the explosive and often moaning expiration. Later the skin becomes dry and pale, and the cheeks flushed, the lips dry or cracked, but seldom presenting herpes. Cough, which may be painful and repressed, is of the hacking expiratory type. The pleural pain is often referred to the epigastrium, but may be correctly localized; and the child seeks a comfortable position, which it abandons unwillingly even to receive fluids for the relief of thirst. The respirations are 40 to 60 per minute, the pulse 120 to 160 or even more, but regular, and the temperature varies from 102° to 105.5°, with slight morning remissions and evening rises. The development of the physical signs may be prompt or delayed. The respiratory murmur loses its vesicular character and becomes rougher, sharper, and of higher pitch until pure bronchial breathing is heard. Fine moist râles and rarely crepitant râles develop. The normal resonance is obscured and becomes marked duliness or dull tympany. The vocal resonance and fremitus is increased. These changes, once inaugurated, usually advance' promptly until the consolidated area in one or more lobes can be clearly defined by physical exploration.

In simple and favorable cases the crisis occurs between the fifth and ninth days, occasionally between the third and fifth days. The temperature in twelve to twenty-four hours drops several degrees to below the normal, with sweating and somnolence, and the child falls asleep to awake greatly improved. The change in the appearance of the patient in a few hours is astonishing—facies, pulse, respiration, appetite, and secretion are all changed for the better; but the signs of consolidation and the cough remain at first unmodified, to disappear with inexplicable rapidity during the succeeding days.

Did all cases follow this classical course, there would be few difficulties in the way of early and complete diagmosis; but there are many anomalies, and it is these variations from the normal which cause us the greatest anxiety, and therefore are of the greatest interest. They may be grouped as †—

- 1. Abortive pneumonia.
- 2. Wandering pneumonia.
- 3. Gastric pneumonia.
- 4. Cerebral pneumonia.

1. The abortive cases begin with all the rational signs of pneumonia, and the diagnosis seems clear, although examination may reveal only modified resonance or slight dullness, rough or broncho-vesicular breathing, and localized râles, when, to our complete surprise, in twenty-four to thirty-six hours there is a sudden disappearance of both physical signs and symptoms, with speedy convalescence. These are undoubtedly instances of localized hyperæmia of the lung tissues which, for some unexplained reason, do not go on to complete consolidation.

Far too little attention has been given in the textbooks to these areas of congestion in the lung which, existing alone, constitute the abortive form of the disease, or which may precede or accompany the development of true pulmonary consolidation. The omission has led to much confusion and lack of self-confidence among those who, seeing children but little, are mortified and disconcerted to find signs which they had one day satisfactorily established, the next day completely absent. These fleeting patches, for whose erratic development and localization we can find no satisfactory explanation, are not confined to the lobar form, but play, as we shall see, a very important part in the course of broncho-pueumonia. The congestion and engorgement of the pulmonary tissue give rise to slight or more marked dullness, to distant or distinct bronchial breathing according to their intensity. Pulmonary relaxation may add a tympanitic quality to the percussion note. Obstruction to the entrance of air may result in decreased respiratory murmur, while the penetration of air into the partly occluded vesicles accounts for the scattered râles.

- 2. Wandering pneumonia occurs under two clinical forms. With a continuous high temperature, daily examinations may show that additional lobes are involved, one after the other, without revealing the advance upon the temperature chart. Again, the temperature may fall sharply, as if the crisis had been reached, only to rise again promptly with the development of signs of consolidation in another lobe, and this may be repeated several times before the final critical fall takes place.
- 3. The gastric cases are most puzzling even to the careful observer, for the attack begins with severe vomiting, anorexia, diarrhœa, and heavily coated tongue, which, together with the referred pain in the epigastrium, lead almost irresistibly to the conclusion that the affection is of gastrointestinal origin. To add to the difficulty, the appearance of the physical signs is usually delayed, a central pneumonia coming to the surface upon the third or fourth day, and often only appearing a few hours before the development of the crisis, which latter, as if to keep up the rôle which has previously been played, is often accompanied by profuse vomiting. To avoid falling into error in these cases, therefore, we must rely upon our observation of the continuous high temperature which does not fall after suitable treatment directed to the alimentary tract, and the evident pulmonary embarrassment, cough, and characteristic respiratory rhythm.
- 4. In a somewhat similar manner the cerebral type of pneumonia is ofttimes misleading, or at the least causes

<sup>\*</sup> The question whether a more exact distinction between the various forms of exudative pneumonia, based primarily on the germs causing them, is not desirable, is one which does not fall within the scope of this paper.

<sup>4</sup> Baginsky. Praktische Beitrage zur Kinderheilkunde, 1880.

great anxiety during the period of uncertainty. The wellknown disproportionate size of the child's brain to its body renders the nervous system especially liable to disturbance in disease, and cerebral symptoms are very common in pneumonia. Although usually not so decided as to obscure the diagnosis, there are other cases where they are so pronounced as to divert the attention from the lungs to the brain, or at least to place us in doubt as to whether there be genuine meningitis, or whether the symptoms are transient and due to the influence of the hyperpyretic blood upon the central nervous system. Early or late convulsions, somnolence, delirium, headache, vomiting, constipation, irregular pupils, strabismus, irregularity of the pulse, retraction of the abdomen, grinding of the teeth, boring of the head into the pillow, may be present in varying combinations. Genuine meningitis, however, is a rare complication. Irregularities and intermissions of the pulse may exist in either disease, but the characteristic pulse of meningitis is slow, not rapid as in pneumonia.

Nervous symptoms quite frequently occur where there is extensive and hence more easily recognizable involvement of the lung and where the temperature is persistently higher than we find it in meningitis. Steiner \*contends that a complicating otitis media may be responsible for many of these symptoms, and cites sixteen cases. From a prognostic standpoint the time of the development of the convulsions is of value, early seizures being of little importance, but late convulsions indicating speedy dissolution within twenty-four hours.†

Returning now to a consideration of the ordinary cases of pneumonia, we find the left lower and right upper lobes most frequently involved. Comparing the two sides, we find the right lung is more often affected than the left, and this preponderance is explained, as in the adult, by the frequent consolidation of the right middle lobe alone.

More than one lobe upon the same or opposite sides may be involved at the same time, or the process may extend to other lobes during the course of the disease. Unlike the adult lung, it is not uncommon for but a portion only of the lobe to show consolidation. The stethoscope high in the axilla will often detect consolidation of the upper lobe which does not reveal its. If elsewhere. With superficial breathing the bronchial character of the breath sounds often disappears. In such cases careful percussion, however, reveals dullness, and if the child be made to cry. the bronchial character returns. Among the complications, bronchitis of the uninvolved lung occasionally supervenes and threatens death by suffocation. Pleurisy is common, and may give rise to pleural friction sounds; it influences the temperature, interfering with the critical fall, and it prolongs convalescence; exudation is revealed by flatter percussion note and lessened fremitus. Large effusions further seriously embarrass the respiration by pressure on the already crippled lung.

Whenever the crisis is unduly deferred or there exist signs of delayed resolution with anorexia and temperature,

empyema should always be suspected and a needle introduced, for in the child bronchial breathing over the exudation is the rule, and if this fact be not remembered the effusion may escape recognition. Abscess, gangrene, and chronic caseous degeneration are rare possibilities. But, in general, the prognosis is excellent, the mortality being only about two per cent. of the cases, which fact further strongly distinguishes them from the next division of the subject.

Broncho-pneumonia is much the same insidious scourge of childhood in the winter months that the diarrheal diseases are in summer. Unlike the lobar form, it chooses as its victims not the strong and well nourished, but the great army of weak, enfeebled humanity who bear the traces of rhachitis, scrofula, and hereditary syphilis, and show the effects of vicious environment, improper feeding, and neglect. It decimates the foundling asylums. It seizes upon those reduced by all chronic or exhausting maladies, and ingrafts itself with especial predilection upon those suffering from measles, whooping-cough, and diphtheria. It is further distinguished from lobar pneumonia by its gradual onset, its prolonged and irregular course, and its slow defervescence by lysis.

Studied in the dead house, it is found to some degree in a much larger percentage of those who come to autopsy than would generally be supposed.\* Almost every portion of the pulmonary structure may be involved, and with kaleidoscopic variety each new case presents a different picture from the last. Trachea, bronchi, alveoli, interstitial tissue, blood-vessels, pleura, and bronchial glands share in the process, some invariably, others but occasionally. The disease is primarily one of the bronchi, both large and small, the mucous membrane of which is congested, swollen, and covered with mucus, while the smaller bronchi are filled with frothy purulent secretion. The inflammatory infiltration is by no means limited to the mucous membrane, but involves chiefly the wall of the bronchus and extends by contiguity to the adjacent alveoli and the intra-alveolar connective tissue. The alveolar epithelium proliferates, and, together with white and red cells and fibrin from the swollen capillaries, is soon present in varying amount in the vesicular spaces. The course of a bronchus is then comparable to the path of a hot needle plunged into pulmonary tissues, searing the adjacent structures as well as its own immediate course. † All portions of the lungs are not affected to the same degree. The process may involve only the bronchus with its terminal cluster of alveoli and its contiguous vesicles, or the consolidation may extend in every direction. It may be limited to small disseminated areas, or it may involve the larger part of both lungs. Every variation between the extremes appears sooner or later upon the autopsy table.

But the consolidation does not always exist alone; three other factors—atelectasis, congestion, and emphysema—one or all, may unite to further disable the already crippled lung. The development of the atelectasis has been ex-

<sup>\*</sup> Jahrb. f. Kinderh., n. F. ii.

<sup>†</sup> Holt. Medical Record, April 7, 1888. Cerebral Symptoms of Pneumonia in Children.

<sup>\*</sup> Small areas are found, especially in the dependent portions of the jungs, in a large proportion of all asthenic and marasmic cases.

<sup>+</sup> Delafield. Pathological Studies.

plained by Gardner \* as follows: Inspiratory efforts draw tenacious secretion or pseudo membrane deeper and deeper into the finer bronchi until it forms a valve like plug at the entrance to the group of terminal alveoli. The residual air contained in the alveoli is then absorbed or else the strong expiratory efforts force it little by little past the obstruction, while the valve-like mass in the bronchus prevents the reentrance of air during the weaker act of inspiration. Gradually the affected portion ceases to be aerated and the collapsed part is rendered useless and practically solid.

Again, I believe that certain hyperæmic areas of the lung may become so engorged and congested as to seriously interfere with the entrance of air into the alveoli and result in a condition which produces the same physical signs and the same evil effects as true consolidation. With the available respiratory surface much decreased, the efforts to expand the chest tend to overdistend the remaining alveoli, and this, aided by the expiratory pressure during cough, when the glottis is closed, may rapidly cause emphysematous dilatation of the vesicles, especially those along the anterior borders, where the lung, being thin, receives less support from the surrounding tissues.

If a lung from an extreme case, combining all these factors, is examined when first removed from the thorax, it presents an instructive study. The anterior borders of both lungs, and especially of the upper lobes, are smooth, tense, and prominent, rising sharply above the adjacent portions and having the pinkish-white color of distended lung. Closer inspection shows that the individual alveoli can be seen by the naked eye, while in places along the edges of the lobes larger distended alveolar spaces are readily apparent, due to the coalition of several vesicles. These emphysematous portions of the lung remain inflated because the natural contractile power of the lung is alone insufficient to drive the contained air through the accumulated secretion in the bronchi.

In close proximity to these emphysematous portions, or even extending into them or surrounded by them, may be seen depressed atelectatic areas, large or small, of a bluish or bluish black color, where the occlusion of one or more terminal bronchi has caused the collapse of the area to which it gave access, while scattered over the rest of the lung are the true broncho-pneumonic areas, often upon the posterior surface and the lower dependent portions, but quite as often elsewhere, around the root of the lung, on the surface between the lobes, in the cardiac lingula, or in the right middle lobe. They are irregular patches of a dark red color which are firm to the touch and have a coarse granular feel, rising above the level of the atelectatic patches but not so high as that of the emphysema.

Around some of these again, and contrasting both in color and resistance, may be seen violet-red areas of congestion, which are readily inflated; but the hyperæmia which has given signs during life does not always persist after death. In some lungs we find small dark areas of

lobular outline which are shown microscopically to consist of groups of alveoli whose cavities are filled with red blood-corpuscles only. These have, presumably, escaped by diapedesis from the engorged capillaries of the alveolar walls, which are seen to be distended with red cells. On section, the broncho pneumonic areas are of a dark or light red, or grayish or yellowish pink, according to their age and the proportion of white cells in the exudate, and by pressure yellow purulent secretion may be made to well up from the opening of the smaller bronchi. Microscopically, the contents of, the alveoli is similar to that in lobar pneumonia, though with less fibrin, but the essential difference lies in the infiltration of the walls of the bronchi and the interalveolar partitions, so that the disease is not only one of exudation but of proliferation.

The atelectatic portions, which are often superficial, vary much in the degree to which the atelectasis is developed. If this is extreme, they have the consistence of muscle, are flaccid, and do not crepitate on pressure, if they contain no air. Theoretically, also, they should for the same reason sink if placed in water, but often enough air remains in bits of tissue to buoy it up. Part of these lobules may still be inflated, although later inflammatory changes usually develop.

While I have given above the outline of what may be considered as strictly broncho pneumonia, it should yet be remembered that there are cases of secondary pneumonia in which the areas of lobular involvement have no connection with the bronchi.

But it is not my desire to dwell upon the pathological or morphological aspect further than is necessary to throw light upon the course of the disease and its physical signs.

The symptoms and course of broncho pneumonia depend so largely upon coexisting conditions, especially in those cases secondary to the infectious diseases, that it is more difficult than in lobar pneumonia to present a classical picture. In the primary cases there exists for a day or two a bronchitis which may be considered the first stage of the disease, and it is noticed that the cough becomes more frequent and hacking, the temperature rises, the face becomes anxious, the respirations more rapid, and the alæ nasi dilate with each inspiratory effort. When the process in the lung has advanced the child lies limply in its mother's arms, its face pale or livid, its skin hot and dry. In nursing or drinking it stops every few moments to struggle for breath. The lips are cracked, and the tip of the tongue often dry. If the chest be uncovered, the respiratory struggle becomes more apparent. Open mouth and dilating alæ nasi do not suffice to give it air. All the accessory muscles are called into play, but the consolidated and occluded portions of the lung can not expand, a partial vacuum within the chest is formed, the episternal notch, supraclavicular hollows, and epigastrium are sucked in with each breath, while deep furrows are formed in the intercostal spaces and the less resistant chest wall is drawn inward along the insertion of the rapidly contracting diaphragm. The respiratory center attempts to substitute speed for depth, and the respirations rapidly increase to seventy to eighty per minute. The pulse becomes 160 to

200. Each advance of the process in the lung, each transitory congestion, each area of collapse, adds to the intensity of the dyspnœa, and, unless relief comes, the respirations become more shallow, the pulse more rapid and feeble, the face assumes an ashen-gray color, and death ensues.

If, however, a happier issue obtains, the pulmonary obstruction decreases, respiration is accomplished with less effort, the sinking in of the chest ceases, the temperature declines from day to day, the pulse improves, the face assumes a better color, appetite returns, and convalescence is slowly established. It must not be supposed, however, that all cases follow these definite outlines or rise to this degree of severity. In no disease of childhood, perhaps, are there so many variations, such sudden changes, such prolonged suspense, such disappointing relapses.

In the above description I have purposely omitted all reference to the physical signs, because no greater error could be promulgated than an attempt to make them conform to any fixed standard. To them, or rather to the exact underlying condition of the lungs, pertains the greatly diversified interest of these cases. Upon the daily, almost hourly, changes in the lung depend the course and the prognosis, our hopes and our fears.

We have inflamed bronchi lined with swollen mucous membrane, filled with muco-purulent secretion, and giving rise to almost every variety of râle, sibilant and sonorous in the early stages, fine and coarse moist sounds in the later. These may be further modified as they come to the ear, depending upon the condition of the tissues through which they pass, and may have a ringing, metallic sound, or be harsh and crackling. Sudden atelectasis may give diminished or absent breathing where before there was a vesicular murmur. Subsequent changes may give rise to modified resonance or dull tympany. Existing atelectasis may disappear as suddenly as it came. The congestion which we found preceding or accompanying lobar pneumonia or existing by itself is even more important here. It may result in partial dullness, with diminished or broncho-vesicular respiration. It may change rapidly from place to place. It may be here today and gone to-morrow. Emphysema even helps forward the confusion and uncertainty, for it may be so near or so surround the patch of true consolidation that its hyper-resonance prevents the recognition of the dullness; and the exaggerated respiratory murmur may completely conceal the faint or distant bronchial breathing. Fibrinous pleurisy, although often present, seldom gives distinctive signs. Enlarged bronchial glands by pressure on a bronchus may cause diminished breathing.

We turn at last to the broncho-pneumonic consolidation for clear and unmistakable signs, but here again we are met with disappointment. We have seen already with what varying distribution and in what diverse forms these areas may appear. Sometimes in narrow zones about the bronchi, sometimes at the root of the lung or between the lobes; again in such small superficial areas as to furnish no clew to its existence, while only a moderate number of the consolidated areas give us definite and unequivocal signs.

You ask me for what purpose I have catalogued the exceptions and emphasized the difficulties. I answer, Because in these very variations unmentioned by the usual text books lie the characteristic feature of the disease. Because the very things which would otherwise puzzle us and cause us to doubt the accuracy of our observations and even the evidences of our senses now point us unerringly to the diagnosis. Because, also, it shows us that we have of late years swung the pendulum too far in the direction of physical exploration and too far away from the careful semeiological inspection of the patient which Fothergill, as one of the last of the old school, tried so hard to impress upon the rising generation. In short, with certain conditions of the temperature and respiration, together with uncertain or shifting physical signs, we may feel as confident of our diagnosis of broncho-pneumonia as if we had discovered unmistakable signs in the lungs.

Let us see, however, whether it is not possible to bring order out of chaos and gain a clearer idea of the physical signs and their interpretation.

The broncho-pneumonic areas may vary from a slight exudation into a few alveoli immediately surrounding a bronchus and showing nothing on inspection, through the grades of larger visible zones about the bronchi, to the extensive consolidation of large portions of the lungs. The process is usually bilateral, though often patches large enough to be seen or to give physical signs are limited to one lung. When the patches of consolidation are small, or superficial, or disseminated, the difficulties are the greatest; when they are large and deep and the signs distinct, there is no difficulty in their recognition.

Exaggerated resonance may be elicited over the apices, especially anteriorly, where the emphysema is most commonly found. Normal resonance, with subcrepitant râles, usually indicates the presence of bronchitis only, but it is, of course, possible that areas of hepatization may be present, though so small or scattered as to add no signs. Much that is of value may be learned from close attention to the râles, for their coarseness or fineness corresponds more or less closely to the size of the bronchi involved, and their number to the intensity of the involvement. Where they are numerous and fine and the respiration embarrassed, we may suspect the presence of disseminated consolidation, although no other signs be present. Modified resonance indicates congestion or hepatization. Distinct dullness may be considered the exception rather than the rule.

A most important matter, however, is this fact: That both consolidation and fleeting hyperæmia give identical signs, and it is necessary to have it firmly impressed upon our minds that only repeated examinations will determine the fixity or mobility of the signs, and so decide definitely with which process we have had to deal. Thus, if the signs of consolidation disappear in twenty-four to forty-eight hours, we know that we have dealt with an area of congestion; but, if it persists, that it is hepatization. While, again, if it comes and goes, and finally returns to stay, we know that congestion, like a troop of horse, has swept hither and thither, preceding and conceal-

ing the main body of true consolidation, which was slowly advancing to occupy the territory.

There are frequent instances in which the atelectasis, congestion, and tenacious bronchial secretion tend to prevent the entrance of air into the disabled lung, there is diminished breathing over the affected area, and the râles conceal its faint bronchial character. In these cases the compensatory efforts of the other lung are attended with loud consonant râles and harsh exaggerated respiration. Here the temptation to the careless or superficial examiner is always to locate the lesion where there is the most noise. No portion of the chest should be omitted in the examination, for the sides and the axillæ, the right middle lobe, and cardiac lingula are as often involved as the apices or the bases.

The temperature charts of broncho-pneumonia exhibit no characteristic course. The febrile period, corresponding to the active process in the lung, is of longer duration than in lobar pneumonia; it declines by lysis, and it shows greater daily variations. Although several charts placed side by side show no special uniformity, there are several general rules which have been deduced after careful comparison of the charts with the record of the physical signs. The extensions and recessions of the inflammatory process in the lung are thus seen to be registered, to some extent, upon the temperature chart. Thus bronchitis of the large and medium-sized tubes causes moderate elevation of temperature with partial morning remissions. When the finer bronchi become involved the elevation is greater, even to 104° or more. Congestion of fresh portions of the lung shows itself by sudden, sharp exacerbations of temperature as it develops, and equally sharp falls when it disappears, the degree depending upon the amount of lung involved and the intensity of the process it accompanies. Hepatization reveals itself only by its tendency to maintain the curve at a more uniform level.\* Thus, as these three factors-bronchitis, congestion, and hepatization-ingraft themselves with varying intensity upon different portions of the lung, they are reflected in an infinite variety of combinations upon the record of the temperature.

The favorable cases, from a prognostic standpoint, are those which run their course between 101° to 104.5° F. Patients with an excessively high temperature usually die, as do those in whom it never rises above 101° F., or is even subnormal throughout. In these latter cases the low temperature seems to be an index of the feebleness and low vitality of the child.

The mortality has been estimated to vary from thirty to seventy per cent., according to the age of the patient and the circumstances under which the disease develops. The younger the child, the greater the danger. Among the primary cases the previous condition and constitution of the patient are important factors. Among the secondary cases the severity and nature of the primary affection must be considered. Cases complicating measles and pertussis give us our highest mortality. Institution children succumb readily; the children of the well-to-do fare the best.

The physical signs are of but moderate assistance, remembering that extensive lesions may be so situated as to give no signs, and that extensive signs may represent superficial and transitory lesions.

It is, after all, to the rational signs that we must turn for our prognostic view of the case. If the respiration becomes superficial, or the cough ceases, or the skin becomes ashen gray, death will ensue if relief is not quickly given. The influence of low and persistently high temperatures we have already seen. Moderate increase of the consolidation is not as bad as extensive congestion or atelectasis. A sudden exacerbation of the catarrhal bronchitis may cause death in a few hours from suffocation.

Favorable cases defervesce in from seven to twenty-one days, though cases may run on for weeks, and the chances of recovery in these prolonged cases steadily decrease with the lapse of time. Resolution requires seven to fourteen days for its completion, for here there is not only the exudation into the alveoli, but the infiltration of the interalveolar connective tissue and the walls of the bronchi, which must be absorbed. Occasionally it extends over a period of eighteen to twenty-eight days. In some instances resolution does not occur for many months and then gradually takes place. In others the walls of the air-spaces become thickened, the alveoli themselves may even be filled with organized tissue, and a chronic fibroid condition results, with contraction of the lung and chest and subsequent dilatation of the bronchi. If the area involved be large, these latter cases, with rare exceptions, do not survive long, but die of intercurrent disease or develop tuberculosis.

Very little time is left us for the consideration of the treatment. As the indications for both forms are similar, they can be spoken of together. Many years ago pneumonia was treated by bloodletting, calomel, and especially on the continent by large doses of the emetic drugs—ipecac and antimony—until Barthez\* stated that in his opinion meddlesome medicine prolonged rather than shortened the course of the disease, if it did not, indeed, largely increase the mortality. A more intimate knowledge of the affection now directs our more intelligent therapeutic efforts. The propriety of prophylaxis needs but to be mentioned. Prompt attention to all minor inflammatory conditions of the air-passages is to be insisted upon and as quickly dismissed.

What, then, is the rationale of the modern treatment of the disease itself? As pneumonia is a self-limiting malady, we adopt the expectant plan of treatment. Temperature, heart action, and respiratory function give us our chief indications for interference. Although the deleterious influence of prolonged high temperature upon the tissues is well known, cases vary greatly in the degree to which they show these evil effects. It is rather the effect of the temperature upon the heart, the brain, and the nervous system which we should consider rather than its height in degrees. Each case must be judged by itself. If it is producing deleterious effects, it should be promptly combated, and to this end the bath or the wet pack are

<sup>\*</sup> Cadet de Gassicourt. Maladies de l'enfance, Paris, 1886.

<sup>\*</sup> Mem. de l'Acad, de médecine, Paris, 1862.

undoubtedly the best measures, for they do not act alone by the abstraction of heat, but are stimulant as well as antipyretic. Not only does the bath produce a subjective feeling of comfort in the patient, but it stimulates the cuta neous vessels, restoring their tone and relieving the overburdened heart; it also calms the central nervous system, removes delirium, favors sleep, and restores the nervous control over the heart and the functions of the other organs.

I have purposely avoided the use of the word "cold" in referring to both baths and packs, for there are conditions where the rectal temperature registers 105° to 106° F., but the surface of the trunk, and especially of the extremities, is cool and the shock of a cold bath would be a source of great danger. The temperature of pneumonia yields more readily to the water treatment than that of typhoid fever, and a bath at 95° F., cooled slowly by the addition of cold water to 85°, or in sthenic cases to 75°, and continued for ten to fifteen minutes, is sufficient to produce a reduction of 2° to 3° in the temperature. Exactness is as necessary here as elsewhere, and the watch and the bath thermometer are as indispensable to the bath as the scale and the graduate to intelligent medication. During the bath friction should be applied by the palm of the hand to the surface of the body, and on removal the patient should be wrapped in a blanket, or sheet and blanket, and allowed to rest for a time undisturbed. Stimulants may be necessary both before and after the bath.

Still better and far more convenient is the wet pack, the child being wrapped up to the neck in sheets wet in water at 75° to 85° F., and covered with a blanket. These may be changed several times at intervals of ten minutes, the last being allowed to remain for half an hour. Twice or three times a day will usually be sufficient. The other antipyreties are not to be entirely discarded, but, if used, their depressant effects must be remembered and they should be guarded by the administration of stimulants.

More important, however, than the temperature is the respiratory function. The danger to adult and child from pneumonia rests upon entirely different bases. In the adult the respiratory muscles are well developed and the strain comes on the relatively weak right heart and the danger is cardiac failure. In the child, however, the two sides of the heart have more nearly the same power, but the thorax is yielding and the respiratory muscles have not reached their full development. Accumulation of secretion in the bronchi, congestion, and atelectasis are therefore especially to be feared. Emetics to empty the bronchi are but rarely indicated, because of their depressant action. This indication is best met by sustaining the strength by proper feeding and the administration of stimulants, digitalis, strychnine, alcohol, or carbonate of ammonia. Congestion should be avoided or combated by counterirrita tion to the chest, by mustard pastes, mustard baths, the application of camphorated oil or turpentine, and olive oil, equal parts, and the use of the oil silk jacket. In some cases dry cups are of great service.

I have only been able to allude hurriedly to these few important factors in the treatment. In conclusion, I desire to compliasize—

- 1. The frequency of true lobar pneumonia in young
- 2. The misleading character of the cerebral and gastric types of lobar pneumonia.
- 3. The fact that pneumonia is often overlooked, and the necessity of repeated examinations of the chest in all sick children, especially of those with persistently high temperature.
- 4. The importance of examining all portions of the chest.
- 5. The very variable distribution and extent of the broncho-pneumonic lesions.
- The importance, both from a morphological and from a clinical standpoint, of emphysema, atelectasis, congestion, and intra-alveolar hæmorrhage.
- 7. The frequent discrepancy between the physical signs and the symptoms of broncho-pneumonia.
- The falsity of the impression that distinct signs of consolidation are necessary to the diagnosis of bronchopneumonia.

# THE DIAGNOSIS OF TUBERCULOSIS BY TUBERCULIN INJECTIONS.\*

BY CHARLES DENISON, A. M., M. D.,

DENVER, COL.,
PROPESSOR OF DISEASES OF THE HEST AND OF CLIMATOLOGY,
MEDICAL COLLEGE, UNIVERSITY OF DENVER;
EX-PRESIDENT OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION;
AUTHOR OF THE BOCKY MOUNTAIN HEALTH ERSORTS;
CLIMATES OF THE UNITED STATES IN COLORS, ETC.

In this discussion of phthisis I think I do well to try to present one phase only at this time, because of the great extent of the field to be gone over.

Then, having settled upon my portion, it may be of interest to you who are present for me to say that by my invitation three physicians should be here with us who have taken either the tuberculin (Koch's) or tuberculocidin (Klebs's) treatments under very discouraging conditions, but with positive benefit, of which any fair physical investigation would give abundant proof.

This is worthy of note, for the virtues of tuberculin have been appreciated by very few physicians, the great majority contenting themselves to go with the strong-current against its use, which set back was the natural result of the first overzealous and too sanguine expectation.

In the absence of uniform positive demonstration in tuberculin's favor, hearsay reports are quite sufficient for doubting minds, and careless statements about reinfection, or the alleged discovery of the *Bacillus tuberculosis* in the tuberculin of Koch by zealous and unreachable opponents in foreign lands are accepted as conclusive evidence of the worthlessness of the new remedy.

This conclusion is reached, notwithstanding the announced method of preparation of the lymph, by heating to 400° F. and filtering through porcelain, a process which is then proved, as we understand, by microscopic examina-

\* Read before the Denver Medical Association and Arapahoe County Medical Society, November 14, 1898. tion, to free the remedy from any germ life whatever. On several occasions I have verified this freedom of the lymph from the *Bacillus tuberculosis*.

It would probably be better if the mistakes of experimenters were attributed to causes which are more within our reach, such as, among others:

- 1. The lack of due discrimination as to which are suitable cases for this particular treatment.
- The indiscriminate dosage, regardless of the favorable conditions and environment necessary to success.
- 3. The looseness and inadequacy of technique in administration and the want of method in recording results,
- 4. The lack of a thorough appreciation of climatic conditions and the defective lung ventilation, especially in bedfast cases and acute phthisis.

It is unfortunate for the affirmative side of any such discussion that this question of *diagnosis* should have to be introduced, but it is really a vital part of the matter.

It is not my purpose to throw undue discredit upon our means of diagnosis of phthisis in its incipiency. Theoretically, so far as our text books go, the profession may seem to be well fortified for the work, but practically, whether due to defective means, method, or conception on the part of the physician, there are too often cases of evident tuberculosis unrecognized till such a time that the most favorable season for arresting the process has already passed.

Without here going into the details of the early physical signs of phthisis, it is sufficient for our present purpose to show that in these uncertain and doubtful cases Koch's new discovery, tuberculin, has the power to bring to our knowledge their true nature and extent with precision and gratifying certainty. For the proper appreciation of this wonderful power some familiarity with or knowledge of the local reaction of the remedy in tubercular lung tissue is necessary. In my report on Tuberculin and the Living Cell to the American Climatological Association in 1892, I reiterated what I believed I had been the first to discover the previous year-that this reactionary effect "consists mainly in a harsh, puerile, or an exaggerated broncho-vesicular breath sound, as heard with the stethoscope over the affected area. This is an exaggeration of what was heard before the tuberculin reaction, or it is heard in localities in which the breath sound was previously inaudible or very different. It is not an evanescent effect, but usually continuous, though in a lessened or lessening degree during the whole course of treatment."

Sometimes this local lung reaction is very feeble, while the systemic reaction, as shown by temperature, pulse, etc., is quite marked and characteristic. The following is an excellent illustration of tuberculin diagnosis in a case where neither the physical signs nor a microscopic examination of sputum could satisfy my decided suspicion that the case was of a tubercular nature:

Case I.—Mrs. K., of Chicago, aged twenty-four years, married four years, height five feet four inches. No inheritance to consumption. Seen a week after arrival in Colorado. Weight a hundred and two pounds, usual weight a hundred and thirty pounds. Gradual loss of weight since a miscarriage two years previously, after which she had la grippe. While at school,

aged sixteen, had dry cough and irritation in the throat thereafter. Free from this two years in Europe, and then worse in 1889. Lately a wheezing and stuffed-up condition toward evening; sometimes had to sit up all night and frequently had to go to an open window at night during the past year. This was evidently a case of complicated asthma, for there was considerable relief of the hard breathing on arrival in Colorado. Expectoration half an ounce per day, dark yellow; cough spasmodic, circulation poor, patient pale, but catamenia regular. Pulse 94, respiration 20, temperature normal. 10 A. M.: Spirometrical record a hundred and twenty five cubic inches; manometer, forty five millimetres. Chest expansion two inches, evenly proportioned to the two sides. The physical signs were not very marked. The expiration was generally prolonged. There was tympanitic resonance over lett main bronchus, and cogwheel respiration and blowing expiration in the left mammary region. Feeble voice sound and broncho-vesicular respiration left apex rear. On the right there was slight dullness and broncho-vesicular breathing front and rear at apex, and voice somewhat exaggerated rear. There were no bacilli in the sputum. The diagnosis was asthma and probably bronchotuberculosis, and it was decided to test the case with tuberculin. The following diagrams show the characteristic tuberculosis reaction to tuberculin, so far as the pulse and temperature are concerned, taken four times a day, according to the method I have employed for three years.

The local lung reactions were first manifest, after the twoand-a-half-milligramme dose, in the left mammary, where the
cogwheel breathing was before, and on the right side, junction
of the third rib and costal cartilage. After the four-milligramme dose these stethoscopic signs were also noted above in
both first interspaces. These sounds were accompanied, when
the temperature rise was great, with decided general reactionary symptoms of slight chill, fever, malaise, and headache. The
sounds, ho wever, at first dry, became softer and less pronounced,
as reactionary signs subsided, till they were about gone at the
sixty milligramme dose, when the patient, much improved in
weight, strength, feelings, and freedom from the old spasmodic
congling spells, did not react, though a rise of ten milligrammes
every third day was given thereafter till a dose of eighty milligrammes was reacled.

Note that the dose can be increased much more rapidly in such a case than in one in whom there are any advanced tubercular lesions in the lungs. In the latter condition, of conrse, such marked temperature reactions should not be tolerated. Note also that the general reactions, as indicated by the temperature rise, reached its maximum on the day following the injections. From this fact alone it is reasonable to conclude that the general dyscrasia exceeds any existing local lung lesion. I conceive that the more rapid capillary circulation in lung tissue—five times more than in the periphery of the body—may account for some of the quick reactions (in three to five hours) in tubercular lung tissue.

In my considerable experience with tuberculin (Koch's), and lately with tuberculocidin (Klebs's), this gratifying diagnosis and result has been exceeded, for certainty of effect, by only two cases, which are worthy of more extended mention than we can give them here.

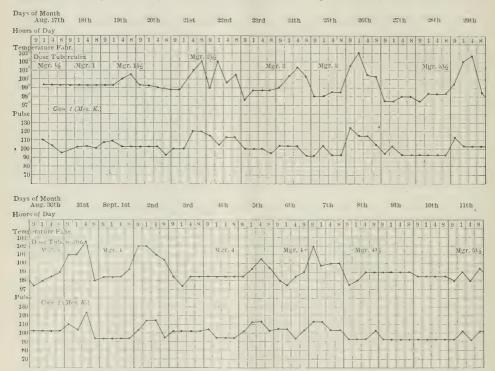

CASE II.—Dr. G., of Vermont, aged thirty-eight years. Positive inheritance, his mother and five sisters, out of seven in family, having died of consumption. His wife had died of tubercular meningitis three years previously, from whom he

may have been infected, as the disease was general in her. He had had a seton put in the back of his own neck twelve years ago for meningitis, which it seemed to relieve, and eight years ago had suffered fracture of the ribs, with septicæmia resulting. Three years ago had la grippe and double pneumonia, chiefly right side. Sick six months. Came then to Colorado, and gained seventeen pounds in as many days.

November 20, 1892.—After a cough in Vermont, had what was termed basilar meningitis; sick since. Headache continuous, and lately very severe up to April 20, 1893, when (in Colorado) the following-described relief came: There was no expectoration to examine, and only slight dullness, lessened movement, fremitus, exaggerated voice, and broncho-vesicular breath sounds on the right side. The temperature, pulse, and respiration were found to be about regular for two days—98.5° F., 60, and 20.

home, where he has been engaged in practice since, enjoying, so he writes, good health. This remarkable case is given as possibly the first diagnosis on record of tubercular meningitis by tuberculin.

Case III.—A case of tubercular arthritis in both knee joints in a young lady of twenty-eight years, who was taken thus while nursing a sister in an Eastern sanitarium, who died of tuberculosis of the bones of the pelvis and spine. Three years afterward, after having tried several kinds of surgical treatment in hospital, the patient referred to submitted to a test with tuberculin at my suggestion. She had lost the use of her limbs and was compelled to use a wheel-chair for locomotion. The reaction at the third, sixth, seventh, and ninth milligramme doses of tuberculin were both general—i. e., headache, malaise, some fever and general distress, and somewhat local in the

respectively—when one milligramme of tuberculin was injected. The genuine diagnostic reaction did not start till twenty-two hours afterward, and then was chiefly general and not local in the lung. It was manifest by temperature 100.5° F. and pulse \$2 to 90, and continued more or less for about fifteen hours, during which at one time he vomited. The day following its cessation a slight increase in dose of tuberculin was given, which was followed, in four to six hours, by a slighter reaction than before. By that time the headache had entirely ceased, and the patient, who had been confined in bed for four weeks, was enabled thereafter to be daily out of doors with comfort. The constriction about the base of the brain, which was marked with the first reaction, gradually disappeared. In less than four weeks, after reaching a dose of thirteen milligrammes and feeling well able to do so, the doctor returned to his Vermont

left lung, where at the age of sixteen she had suffered some slight disease.

Seven months after this diagnosis an attack of la grippe seemed to center the tubercular poison in the glands on the left side of the neck, which, being removed, showed tubercle bacilli in giant cells in the center. This confirmation of the previous diagnosis led to a continuance of the tuberculin treatment in Colorado from October, 1892, to May, 1893. The result has been successful, for the young lady, now in Vermont, enjoys excellent health, and walks considerable distances without her crutches.

Other instances of decided diagnosis of tuberculosis if cited would include two cases of tubercular ulceration of colon; lymphadenoma, with general glandular involvement; scrofular cases (glandular); and supposed pulmonary fibroses.

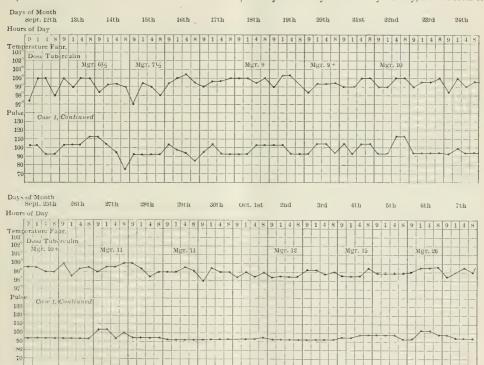

An important consideration to be drawn from some of the above and other of my cases is that there is an active tubercular stage—pretubercular, if you wish to call it so before the bacillus of tubercle makes its appearance as a factor in the case, so far as we are able to judge.

I do not refer to such manifestly tubercular cases as where the full picture of an acute phthisis is given, excepting the bacillus of tubercle microscopically demonstrated in the sputum, perhaps as with a young lady patient I have in mind, whose expectoration was loaded with spores one week, and the next gave fifty bacilli "to the field," the first found in her case. Nor is reference in-

state to bring great credit upon him who will elucidate this interesting and important problem.

Among the phases of this subject to be solved, the following appear to me to be urgent: \*

1. Minute explanations, on pathological grounds, of the adenoid growths in the region of the third tonsil, such as have been known to be removed ad infinitum by specialists, and no microscopic evidence of bacilli found either in the flesh removed or the patient's expectoration. Yet the patient goes on to die of laryngeal tuberculosis, as the gradually increasing peribronchial and apical infiltration and consolidation (immediately following the surgical interference in the throat) indicated what the result would be. Such a case is just now very distinct in my memory, and will recur to

tended to be made to other cases where active tuberculosis can be inferred as going on away from the bronchial tract, and the more acute and septic on that account—i. e., because the bacilli are not thrown off. But reference is intended to those intricate slowly acting blood changes which come under the classification of dyscrasiæ, which may be, for all we know, the sine qua non of the bacillus of tubercle's existence, that state which may indicate the more or less complete annihilation of the body's natural antagonism to this particular foe.

If our judgment and means of knowing the first appearance of the bacillus are not wholly at fault, then there is certainly enough in this idea of a definite pretubercular the mind of the distinguished physician who kindly recommended the case to me, but very unkindly and, I think, unwisely prevented my afterward using tuberculin in the case, the only means I know of which would have compassed a cure, however incomplete that would have been. The prejudice in the minds of some of our best physicians against even the advanced and enlightened use of tuberculin is as unreasonable as it is alarming.

2. An understanding of the absence of tubercle bacilli,

<sup>\*</sup> These considerations and some other parts of this essay are taken from my paper on The Early Diagnosis of Phthisis, etc., lately read before the Section of Hygiene, Climatology, and Demography of the First Pan-American Medical Congress held in Washington, D. C.

or their tardy and very infrequent appearance, compared with the amount of glandular growth in so-called scrofular glands, with or without a coincident active tubercular process in some other part of the body.

3. An understanding of the growth of tubercles—the "nodules" which have come down to us (previous to the discovery of the bacillus)—as the essential feature of phthisis.

As elsewhere explained in the essay on tuberculin, etc., previously referred to, I have myself a strong belief that these tubercles are the natural prison vaults built for the incapsulation of the tubercle bacilli, in which condition the germs, if not strangulated, are held so much in quiescence that they are incapable of propagation or further harm. This is a condition of arrest while it lasts, while the natural resistance of the system is maintained, which is, perhaps, about all Nature can do in the direction of a cure. But the natural effort to maintain the integrity of the living cell is all the time active, and its mention here is made solely with the hope that some more worthy investigator will by its means—i. e., on natural gounds—elucidate for the medical profession the intricate problems here suggested.

The late distinguished president of the Royal College of Physicians, London, Sir Andrew Clark, with his usual diagnostic acumen and literary ability, formulated an elaborate argument opposed to the ideas of Professor Koch and his followers, but in favor of a bacillary and a non-bacillary classification of phthisis. How large a proportion of Sir Andrew's " non bacıllary" class, including his purely fibroid variety, would have had to be transferred to the bacillary division is of course conjectural, but I suspect they would have constituted the total or a very large percentage had those cases been tested thoroughly with tuberculin injections. In my own experience it has been very largely the chronic bronchorrheas and bronchiectatic cavities, of all the chronically affected lung patients daily expectorating vellow matter, which have shown neither bacilli in the sputum nor reaction to tuberculin injections. The failure to find tubercle bacilli in the sputum is certainly no adequate proof that tuberculosis does not exist. This statement will be accepted as true by every reflective mind, but upon me its validity has been impressed by eight or ten diagnoses by the aid of tuberculin injections similar to the first case given in this paper. In some of these, during the first part of the treatment, bacilli were found in the expectoration, which evidence again wholly disappeared as treatment progressed. But for such a diagnostic means the extent of latent tuberculosis among the people who walk our streets remains, as it always has been, a mys-

Very likely an impression may be given that climatic influence may not be duly accredited in the foregoing effects, and it is extremely probable that neither the composition of tuberculin nor of the Klebs or Hunter modification of it are the best and safest possible. Like others, I look for something better, but, until that is found, I am glad that we have in tuberculin so good a referee to decide, in doubtful cases, if tuberculosis exists.

#### PEPSIN

AS A THERAPEUTIC AGENT IN SURGERY.

By THOMAS O. SUMMERS, M. A., M. D., F. S. SC. LOND., ETC., WAUKESHA, WIS.

Or all the therapeutical agents with which surgery has been recently flooded, there is none which has commanded greater attention and given greater satisfaction to the surgeon than pepsin in its application to diseased skin and mucous surfaces. Of course, ever since it was known to physiologists that the active principle of the gastric juice was a dialytic agent that acted merely by its presence without entering into any chemical relationship with the affected substances, it has also been known that pepsin had a peculiar elective affinity, separating non-vital from vital tissues with an accuracy of differentiation equaled only by chemical affinity itself. It is indeed strange that so long a time was allowed to pass in the history of medicine in which pepsin was not known as a therapeutic agent in surgery. although its action upon tissues had been so thoroughly demonstrated in physiology. My own experiments began in somewhat of a tentative way at the Pathological Institute in Berlin during the spring and summer of 1875. I was first led to its use while preparing tissues for the microscope. Being constantly troubled in my histological work by the presence of the debris of cell action which often obscured the definition of the structural cell under investigation, I cast about for something to clear away from the tissues everything but the vital structure, if I may so call it for present convenience, and I found this in pepsin, which effectually removed all the products of cell life-the formed material investing the active cell-and enabling me to produce a clear unobstructed view of the special cell of the structure under observation. From this I passed on to its use in pathological work, where I found it even more valuable in eliminating confusing elements. In many cases I must say, however, I failed in getting good results, on account of the inferiority or impurity of the pepsin used, and I have since attributed much of the skepticism of the medical profession and its hesitancy to accept with enthusiasm so valuable a therapeutic adjuvant to this very fact-the nature of the pepsin used, many preparations being so weak or so adulterated as to render the dialytic action outside the stomach almost inappreciable. and often indeed adding new complications to the microscopic appearance of the tissues. In embryology especially did I derive much value from peptic washings, and I have often received from the much-esteemed Dr. Orth, of Berlin, very flattering commendation for clearness of definition which I obtaized by this use of pepsin, without informing him of my methods, as they were not those which he recommended himself. It was but a step from this use of pepsin to its therapeutic application, and one must have been blind indeed and passing dull who failed to follow a path so clearly blazed. However, as I was then wholly at work upon histological and pathological investigations, I reserved my observations upon this point to a time when I should have the opportunity to demonstrate the practical

value of the therapeutic use of the agent to which I had been so much indebted for clearing up difficulties in cell differentiation. Just as is the case with most discoveries that are allowed to sleep-some one comes along and wakes them up-so with this. Some time after, when, in the activity of practical life, I had allowed the dust to settle upon histology and pathology, I was startled into a regretful sense of my negligence by noting in some of my journals accounts of the use of pepsin in indolent ulcers, in the removal of neoplasms and adventitious tissue of various kinds, etc. This stirred me into a regular series of experiments with pepsin as a local application to inflamed and otherwise diseased mucous membranes, and while I lost the right of discovery by my failure to follow up the legitimate inductions of my microscopical work, I was nevertheless enabled to demonstrate the value of an agent which I believe is destined to stand in the foremost rank of modern surgical therapeutics. No one who has not seen the change produced by the thorough peptonization of the whole surface of a jagged, lazy, indolent ulcer that has resisted every effort to excite granulation and awaken the dull vitality of the surrounding tissues can fully appreciate the immense possibilities of such an agent. The pale, livid edges light up with the reddening fires of vitality, wavelets of granulation swell up over the surface of the lesion, and soon healthy tissue reaches out cellular arms across the chasm and repair is rapid and complete. This is no fancy picture, as every one knows who has seen it and as every one may see who tries it. Then came the use of pepsin in eczematons eruptions, founded upon the same therapeutic principle, many of which seemed to vanish as if by magic at the first thorough peptic saturation. Mark the word saturation, for it is that which is required to get satisfactory results-a regular pepsin poultice, if you please-for here let me remark, it is to this namby-pamby dillydallying with remedies of pronounced effect that damages their character for activity in many cases.

Having found pepsin thus efficacious in the treatment of eczema-which, by the way, is made to cover a multitude of dermatological sins-it was natural to try its effect in other skin diseases, and whenever there was an exuberance of morbific cellulation, it always rewarded the experimenter beyond his most sanguine expectations. But I thought I had found the philosopher's stone, indeed, when I pushed my a priori therapeutic forces into the realm of venereal pathology, and, in a fit of desperation over a case of protracted gleet that seemed to be proof against the whole pharmacopæia, I took the patient, a very unusually submis sive character, into my confidence, and proposed the digestion of everything in the urethra, from the meatus to the bladder, before applying anything else. To the astonishment and delight of us both, the effect was magical, and, after two or three applications, the case was cured. I say I thought I had found the philosopher's stone of therapeu tics, as nowhere in the medical journals had I seen any account of such a use of pepsin, and I immediately began to experiment with various combinations, in all of which pepsin was the digestive agent, and, after finally preparing one which met all the indications for general use in gonorrhea,

gleet, and stricture, I was ready to create a great therapeutic sensation by announcing it as my own discovery, as indeed it was, so far as receiving any outside suggestions was concerned, when a letter from Messrs. Armour & Co. informed me that they had been recommending such a use of pepsin for "two years past," While this announcement threw a little cold water on my enthusiasm, I was glad to have my investigations and their results confirmed by the suggestions of the gentlemen whose preparations had enabled me to do so much in this line of therapeutic work, and it is more especially to this action that I desire to call the attention of the profession, for there is nothing that will be hailed with greater satisfaction and joy by the practitioner than something which may be relied upon rationally as almost a specific in the cure of these troubles, which are the very bane of his life, and which do more to unsettle confidence in his skill and ability than anything else in his professional career. And without hesitation I can offer him this, which I have yet to see fail in a single instance to produce the results expected, however complicated the

I have had prepared for me a bougie lubricator, put up in boxes for office use, and I now never insert a bougie that is not thus peptonized, as it were. This ointment is adaptable to skin diseases, especially those of the itching variety, the pruritus disappearing frequently after the first application. I have also had prepared urethral, vaginal, rectal, nasal, and aural soluble bougies, made of pepsin and boric acid, with an active permeable menstruum by which cavities can be reached and treated locally.

In conclusion, I can not too strongly urge upon the profession the use of an agent that, in my hands, has produced such unvarying good results, and to the use of which fewer objections can be urged.

The following is the formula I use and the accompanying treatment:

- 1. Wash out the urethra thoroughly (always after urinating) with plain hot water, as hot as may well be borne.
- 2. With a syringe having a soft rubber, conical-shaped nozzle inject the following:

Injection No. 1-

Ιý	Tepsin (Armour's)
	Ac. boracici gr. xx;
	Infus. vaccin. macrocarp. (made
	from cranberries) = j;
	Aq. dest, — — — — — — — — — — — — — — — — —
1.	Sig.: Inject every three hours the first day.
nj	ection No. 2—
	2

After this, alternate the prescriptions until entirely cured, using the ordinary dietetic measures indicated in such troubles.

I shall be pleased at any time to answer any questions from physicians or pharmacists with regard to the preparation of this formula, and explain any difficulties that may arise in compounding it. I have mentioned Armour's pepsin because, while it is far from my purpose to say anything that would savor of special pleading, it is only just to say that all of my work has been done with their preparations, and they have aided me in furnishing facilities for bringing it properly before the profession.

#### CONTRIBUTION TO THE

STUDY OF THE SIMULTANEOUS DEVELOPMENT OF TWO DIFFERENT EXANTHEMATIC DISEASES.

BY B. S. TALMEY, M.D.

It is the duty of every practitioner to make critical use of his own observations gathered at the bedside. The more numerous the publications, the more clearness they will bring and the better judgment they will create, particularly with reference to diseases about which there exist different views. I make the following communication with two purposes: the first, to give a contribution to the simultaneous development of two different acute exanthematic diseases; the second, to show to the medical profession the excellent results following the use of cold baths in acute infectious diseases.

Twenty years ago the possibility of two simultaneous exanthematic diseases was much discussed. The simultaneous development of scarlatina and varicella especially was a point in dispute because many observers, among whom were no lesser men than Hebra (Virchow's Handbuch d. spec. Path. u. Ther., vol. iii) and Trousseau (Clinique méd., vol. i), denied its existence. They considered the exanthema preceding the varicella which was described by other observers as due to scarlet fever as the prodromal rash of varicella which is almost regularly found as a diffuse dark-red eruption occurring in large patches. At the same time a number of prominent physicians published several cases of simultaneous exanthematic diseases, of which I will only mention cases of scarlet fever associated with varicella. L. Thomas (Jahrbücher für Kinderheilkunde, vol. iv) published two cases: One, a child aged fourteen years, was seized first with varicella and then with scarlet fever; the other, a child aged one year and nine months, at first with zearlet fever and then with varicella. Henoch (Vorlesungen über Kinderkrankheiten) also saw two cases-one a boy nine vears of age with varicella first and scarlet fever afterward, the other a child aged four years with scarlet fever at first and varicella later on. Hirschsprung saw a girl eight years of age with scarlet fever at first and then with varicella. Brunton (Glasgow Med. Jour.) published a case of a child aged four years with varicella and scarlet fever successively. Matray (Wiener medicin. Wochenschrift, 1878, No. 78 and 79) describes a case of a boy, three years old, with varicella and subsequently scarlet fever. Galliard (La médecine moderne, 1891, p. 491) saw a case of scarlet fever followed by varicella. Hüttenbrenner (Lehrbuch für Kinderheilkunde) says: "There is no reason why we shall a priori deny the simultaneous occurrence of scarlet fever and varicella." The bacteriological experiments published about mixed infection by Frankel and Feudenberg (Ctrlbl. f. klin. Med., 1885, No. 45), Cooke (Fort-

schritte der Medicin, 1885, No. 20), Heubner (Ueber die Scharlach-Diphtherie, Leipsic, 1888), Lenhartzt (Jahrbuch für Kinderheilkunde, vol. xxviii), also show the simultaneous existence of several pathogenic bacteria in the human body. In fact, numerous cases of a combination of two or more exanthematic diseases have been published. Clinicians have, therefore, long been familiar with this fact, though the cases are not very frequent, and we must bear in mind that many of the cases published as scarlet fever combined with another exanthematic disease were incorrectly diagnosticated and the so-called scarlet exanthema was only the prodromal erythema of the disease following it. Still, there are many cases among them which show beyond any doubt the real existence of scarlet fever combined with another exanthematic disease. My present case also does not admit any doubt as to the right diagnosis. The history of the case reads as follows:

On Wednesday, November 23, 1892, I was called to Charles F., eight months old, who was suffering from sleeplessness and fever, and my diagnosis was scarlet fever. In order to avoid the infection of their older boy, the parents sent the sick child to the hospital. The next day the rooms were disinfected by the Board of Health, notified by the physicians of the hospital.

On Sunday, November 26th, the child died at the hospital. In spite of the precautions taken by the parents, their boy, Lewis F., two years and eight months of age, was suddenly taken ill on December 2d. I was again called and found status præsens: A healthy-looking, well-nourished child; numberless small red points densely crowded and united into a diffuse intense scarlet erythema on the neck, chest, abdomen, and flexor surfaces of the extremities, and pallor of the lips and chin. The rash was the characteristic exanthema of scarlet fever. The temperature was 39° C. (102.2° F.). The tongue had the wellknown raspberry appearance. Inspection of the throat showed the fauces intensely congested, dry, but no membranous deposit. The child was extremely prostrated. It was continually somnolent and apathetic. There could be no mistake as to the diagnosis of scarlatina. The infection from his brother, who had died six days previous from scarlatina, confirmed the diagnosis. I ordered cold packs around the neck and chest and a dose of calomel on account of constipation.

In the evening of the same day the patient felt much better. The next day he was worse. The rash had now spread over the entire body. The same apathy and somnolence existed as on the previous day. There was a fresh rise of temperature to 41° C. (105·8° F.). I had to take heroic measures, and ordered gradually-cooled baths which I prepared myself. I gave from this day two to three baths daily, and succeeded in lowering the temperature by 2° C. after every bath. Apart from the baths, the patient took during the afternoon 0·5 gramme of quinine. On the 6th of December the scarlatinal rash had almost disappeared. The temperature was not higher than 37° to 38° C. The somnolence had ceased and the patient could now be considered as convalescent.

But on December 8th another rise of the temperature to  $40^{\circ}$  C.  $(104^{\circ}$  F.) set in and the somnolence reappeared. The examination of the body revealed the typical eruption of varicella. The vesicles were of the size of a pea, several somewhat larger, with a small red areola. The vesicles developed upon the back, neck, a few upon the scalp, and one or two upon the mucous membrane of the mouth. There could not be any doubt about the diagnosis of varicella, particularly when, during the following days, repeated eruptions of fresh vesicles were found

by the side of others which were drying up. I ordered the cold baths again and continued them during the fever period.

The amount of the urine during the afebrile period, from the 12th to the 17th, was diminished almost to complete anuria. I suspected, therefore, though I could not find any albumin in the urine, that nephritis was developing. My suspicion was justified. On December 17th the temperature rose again to 41° C. (105.8° F.), and on examination I found the urine turbid and high-colored, containing about one per cent. of albumin. The patient exhibited uremic symptoms. I administered digitalis combined with kali acetici, calomel, and ordered hot baths—about 40° to 45° C. (104° to 113° F.). Until December 24th the patient was in a very critical condition. From that the temperature fell, and after three weeks the albumin in the urine had entirely disappeared.

The above-mentioned symptoms show the correctness of the diagnosis of combined scarlatina and varicella. The presence up to that time of an epidemic of scarlet fever in the city, the infection from the first child which had died from scarlatina in the hospital, the development of severe nephritis on the fifteenth day of the disease, and the character of the exanthema, do not admit any doubt as to the diagnosis of scarlatina. The diagnosis of varicella from the second rash was also plain to any practitioner who had but once seen a marked case of varicella.

I therefore desire to make but a few remarks as to the time of acquirement of the two diseases. Did the patient acquire both diseases at the same time from the same individual, or did he acquire them successively? Scarlatina appeared on the ninth day after the departure of the first child from home, varicella on the fifteenth day. Since the incubation period of varicella lasts from thirteen to sixteen days and that of scarlet fever generally from five to eight days, I have no doubt that the infection of both diseases took place at the same time. I also think that if the first child had not died on the fifth day of his sickness we might have also observed an outbreak of varicella on his body.

I mentioned above that I intended to show by this paper the wonderful results attained by the administration of gradually-cooled baths in acute infectious diseases. The reader, after careful perusal of this article, will admit that the patient was in extreme danger. The severity of the exanthematic diseases varies in different epidemics. During some epidemics almost every case is severe. Our patient acquired his disease from his brother who had died within four days. It could therefore, a priori, be expected that this child would also die. I am convinced that the life of our patient was saved only by the cold-water treatment. The cold baths have not only a powerful and beneficial effect upon the nervous system, and particularly upon the circulatory nerve centers, but they influence also the temperature in acute febrile diseases, as I have observed in hundreds of cases I treated during the time of my assistanceship at the Royal Polyclinic for Children's Diseases of the University of Munich. Particularly in exanthematic diseases in which an inflammation of the respiratory system is to be feared, the cold baths are the only treatment from which we may expect a satisfactory result. I did not derive great effects on the temperature from cold applications to the head, neck, chest, and abdomen, neither from cold packs, though they benefit greatly the pulse, cyanosis, respiration, and cerebral disturbance. I would therefore recommend to every general practitioner to make more use of gradually-cooled baths as applied by Professor von Ziemssen in typhoid fever. It is to be extremely regretted that in this country the parents and relatives of the little patients, when a cold bath is but hinted, are shocked and oppose the baths with all their power. If physicians make very little use of this powerful remedy the laymen do not get accustomed to it. In practice among the poor particularly we can, by administering cold baths, spare them many dollars which are carried to the druggist for antipyretics and expectorants.

Also in pneumonia I prefer the cold baths to any other treatment. Some time ago I saw a case of pneumonia in a child aged fourteen months. The father, himself a physician, would not allow me to use the cold-water treatment until the child was almost dying. At last he submitted, and the child recovered. The shock received by the child at the moment it is placed in the cold bath makes its breathing deeper and causes it to expectorate the mucus which remains in the bronchi during the superficial respiration in febrile diseases. The baths are therefore a preventive measure against the spreading of an inflammation in the lungs. Now, in all exanthematic diseases the lungs are apt to be affected. The cold baths are therefore the best means of preventing it.

140 WEST SIXTY-THIRD STREET.

Dr. Morris's Operation for the Removal of the Vermiform Appendix.—By an accident, the cut illustrating Dr. Robert T. Morris's lecture, published in our last issue, was turned so that the top lay to the right and the bottom to the left. We learn that the error has puzzled some of our readers. To appreciate the cut, hold the journal sidewise with the head of the page to the left.

The Harvard Medical Society of New York City.—At the meeting held on January 27th the following officers for 1894 were elected: President, Dr. Reynold W. Wilcox; vice-president, Dr. Royal Whitman; secretary and treasurer, Dr. Dillon Brown; executive committee, Dr. J. Winters Brannan, Dr. Frank H. Daniels, and Dr. Howard Lilienthal.

Mounted Nurses in India.—A monthly allowance of thirty rupees is granted by the government in India to women nurses, employed on field service, for the keep of a horse, provided that during the period of such service a horse or pony is actually kept and used. The horse or pony is granted free conveyance from place to place whenever the assignment of the nurse is changed.

The First Japanese Lady Physician has recently been licensed to practice in Nagasaki, according to a Dutch journal cited by the Deutsche Medizinal-Zeitung. The lady's name is Marie Saganiana, and she is said to have obtained her medical education in Ohio.

The Marine-Hospital Service.—A board of medical officers will meet on Monday, April 16, 1894, in Washington, D. C., for the purpose of examining candidates for appointment to the grade of assistant surgeon in the Marine-Hospital Service. For further information address the supervising surgeon general, United States Marine-Hospital Service, Washington, D. O.

THE

## NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by FRANK P. FOSTER, M. D

NEW YORK, SATURDAY, FEBRUARY 3, 1894

#### THE ATTITUDE OF THE STATE COMMISSION IN LUNACY

It would seem as if the New York State Commission in Lunacy had deliberately set out to bring contempt upon itself and disgrace upon the noble charities of this State. We recently pointed out the unfortunate political proclivities of the Commission in Lunacy, and the apparent object of this body to evolve itself into an enormous political machine. On all sides in the State these tendencies have been subjected to severe criticism from honorable men of every profession, and the voice of reproof grows louder every day as the lowering ambitions of the commissioners become clearer and clearer. In spite of these ominous warnings, the commissioners grip more firmly the rein of power already in their hands. Indeed, they seem disposed to use their authority to crush those who oppose the evolution of the political machine. Among the men who have openly and fearlessly discussed the positions taken by the commission is Dr. G. Alder Blumer, of the Utica State Hospital, one of the ablest superintendents of this State. In retaliation for this the commission stultifies itself thoroughly by an organized and vindictive persecution of Dr. Blumer. It is pretended to show that Dr. Blumer was not regularly appointed through the Civil Service Bureau of the State, and an attempt is made to wrest from him the conduct of the American Journal of Insanity, which has been published at the Utica Asylum for fifty years. In an interview published in the Utica Daily Press, Dr. Blumer makes the following statements:

"I have set my face resolutely against the attempted injec tion of politics into the management of State hospitals, and I have not hesitated to raise my voice and use my pen in behalf of local autonomy, under the wise management of trustees of high character, nominated by the Governor and confirmed by the Senate, subject, of course, to proper State supervision and inspection, and against a centralized despotism composed of two laymen and one medical politician. I have insisted upon my rights as the chief executive officer of a great public charity, and dared to decline to be regarded as a cog in what bids fair to become a monster political machine. My independence has cost me a good deal, but not more than it is worth. The story is too long for an interview, but, as aptly illustrating the animus of the Lunacy Commission, I should like to say a word about the American Journal of Insanity, a publication established in 1844, of which I have the honor to be editor in chief. Ever since the present Commission in Lunacy came into existence that journal has been a thorn in its flesh, because, forsooth, it has striven to live up to the claim of its title to nationality and has stoutly refused to lower itself, on demand and threat, to the grade of a servile organ of the Lunacy Com-

mission. Several futile attempts have been made to wrest the editorship from me, but the latest of them so well exemplifies the high-handed methods of the commission that it is worth mentioping. It came in the shape of an opinion of the attorney general's office last October, to the extraordinary effect that, whereas, under chapter 214 of the laws of 1893, it was for the State Commission in Lunary to pass upon supplies for the State hospitals, and revise estimates, as to quantity and price, it followed of necessity that it was also within the province of the commission to determine the propriety of a superintendent's devoting a portion of his time to editing medical publications. Under this rule the Lunacy Commission has already begun a policy of starving a scientific medical journal that has flourished, to the honor and credit of the Utica hospital, for fully fifty years. The superintendent's right to utilize his leisure time in editing, without pecuniary reward, a publication in the line of his professional work is questioned, but the president of the Lunacy Commission may be hired to testify in a Field case, without let or hindrance, imposed by either officer of State or conscience, and quietly pocket his fat fees, while the legal member of the commission permits himself the privilege of lecturing at Cornell University and the faculty that of paying him for his services, to say nothing of numerous ex parte articles prepared for the lay press on the lunacy situation as viewed from the southwest corner of the Capitol."

We can only say that it is unfortunate that this State, after years of prosperity and happy fame in the management of its great charities, should have its good reputation thus dragged in the dust. But the board's action is pretty sure to work its own destruction.

#### MINOR PARAGRAPHS.

#### MEDICAL SOCIETIES TOO EASILY FORMED.

THE Cleveland Medical Gazette, speaking for the State of Ohio, remarks upon the too facile formation of medical societies. Every plausible pretext, it says, that can be hunted out is made use of in order to form all sorts of district, State, tri-State, national, railway, and specialistic bodies. And the men who "run" these societies are too frequently men of no real scientific attainments, and not always respected at their own homes. "In fact," it says, "they are too often the men who are in bad odor and who do not hold the esteem and respect of those who know them best, and consequently are obliged to go away from home, where they are not known, in order to secure these positions of honor. Not intrequently these men manipulate the State and national organizations for their own purposes as long as possible, and, when they are found out and turned down, they go off and organize a new society. And the pity of it is that the respectable, well-meaning, intelligent, scientific practitioners will go into these new organizations and lend to them a cert in respectability; and, in fact, without the labors of these unselfish members of the profession they could not exist." The lesson from all this is that every physician who wishes to have his weight of influence telt should examine carefully the claims of all newly launched organizations, as well as ascertain the standing of their office-bearers, before embarking in them. If any socially inclined practitioner were to set out to join all the societies that appeared to have a claim upon him, if he were faithfully to go to all their meetings, and if he were to respond to apparently reasonable demands upon him for "papers or cases," he would have very little time left to get together "the sinews of war."

#### THE LOCALIZATION OF FACE MOVEMENTS.

Dr. Brissaud recounts in the Progrès médical some recent investigations of his on the cortical localization of face movements in man. His subject had exhibited recurring attacks of right hemiplegia, facial paralysis, and aphasia during life. An autopsy revealed the following conditions: Situated in the superior sulcus of the left insula, immediately posterior to the frontal operculum, there was a soft vellowish mass. It was apparently superficial, but on microscopical examination there were found to exist on the internal border of the left peduncle a number of granular bodies. A very careful inspection of the brain showed no other focus of degeneration. The frontal region of the left hemisphere presented several anomalies, but the line of demarcation between the healthy tissue and the lesion was easily made out. The author had no doubt that this lesion was the cause of the facial hemiplegia, but, according to the localization of leg and arm movements by other observers. there was no lesion of the brain to account for the paralysis of those members. There was an involvement of the orbital and frontal muscles, but this was explained by the continuity of the fibers of the projection system. It was thought, considering the very small focus of the lesion, that the deduction from this study of the center of localization of face movements in man was unique. The author definitely located this center on the ascending parietal operculum, immediately posterior to the inferior extremity of the fissure of Rolando.

## CHLORINE WATER IN THE TREATMENT OF GONORRHGEAL OPHTHALMIA.

THE British Medical Journal for January 6th cites Burchardt as favoring the use of chlorine water, followed by that of nitrate of silver in solution, in the treatment of acute purulent ophthalmia of gonorrhead origin, in adults as well as in children. Formerly he carried out the classical routine of leeching, scarifying, cauterizing with nitrate of silver, and ice compressing. These have been dropped by him, one by one, because either they produced all effects or they appeared to him irrational. He now relies on a free irrigation of the inflamed sac with a five-per-cent, solution of chlorine water. This is followed by a one-tenth-per-cent, solution of nitrate of silver. The patient's head is held back so that the face is directed upward; an assistant allows the solutions to fall into the inner canthus drop by drop, while the surgeon moves the lower lid up and down with his thumbs and moves the upper lid more slowly with one of the fingers. In this manner he is able to clean out the sac very completely. The success of the method, according to Burchardt, appears to lie in the free movement imparted to the lids, whereby the solutions gain contact with every fold of the conjunctival membrane. Shreds or membranous patches are removed from the conjunctiva after everting the lids.

#### PSEUDO-DIPHTHERIA.

An interesting case of recurring false membrane of the throat is reported in the Journal of Laryngology, Rhinology, and Otology for December, 1893. The condition of the throat as it first appeared was that of a diphtheritic affection, but thorough microscopical examination of the membrane excluded this diagnosis. The patches of yellowish membrane covered

portions of both tonsils, the uvula, and half the soft palate, and the area immediately around the exudate looked red, vascular, and slightly edematous. The whole membrane could be detached without hemorrhage or immediate reformation, and the underlying surface became quite healthy and normal in a few days after its removal. There were no constitutional disturbances or even functional derangements. The curious teature of the case was the recurrence of the growth at intervals of from fourteen days to two months for nearly two years. Every effort to discover the cause of the trouble or to arrest a recurrence of the condition had failed. The only changes noticed were the tendency of the affection to spread toward the tongue and its not recurring so frequently in the pharynx. The case was under the charge of Sir Philip Crampton Smyly, of Dublin.

#### A NEW ALLY OF THE ANTI-VIVISECTIONISTS.

Can it be that M. Coquelin is at heart an enemy of experimental pathology? At the close of a recent rendering of Les surprises du divorce he is seid to have made a remark that possibly will put him on the defensive in this regard. The audience encored the comedian, and after a slight delay he complied. The Herald says: "No wonder the audience was loath to go. And those who stayed a few minutes were well rewarded, for he came out and gave, with the diction that is peculiarly Coquelinesque, a favorite monologue of his, La Chasse, where he gayly avows 'Le plus que j'étudie les hommes, le plus que j'aime les animaux.'" There is an older saying, among the French, sometimes ascribed to Montaigne, that expresses a similar cynical feeling—namely, "The more I know about politicians, the better I like dogs."

#### AN ADVERTISING MISREPRESENTATION OF A PHYSICIAN.

Dr. Allan Molane Hamilton has sent us a copy of an advertising circular issued by the makers of a proprietary medicine purporting to consist of an article written by Dr. Hamilton, of which, however, he denies the authorship. He naturally protests against such a use of his name, and, we think, with good reason.

#### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 30, 1894:

DISEASES.	Week ending Jan. 2%.		Week ending Jan. : 0.	
Diseases.	Cases.	Deaths.	Cases.	Deaths.
Typhas	0	()	0	0
Lyphoid fever	7	7	- 6	5
Scarlet fever	116	9	129	3
Cerebro-spinal meningitis	()	-1	- 0	()
Measles	605	20	530	18
Diphtheria	225	บอั	210	71
Small pox	27	:3	27	2

The Methodist Episcopal Hospital, of Brooklyn,—This hospital has received a donation of \$5,000 under the will of the late Mrs. Lucy Williams, of Pittsfield, Illinois. The gift is designed to endow a bed.

The German Hospital, of Brooklyn,—The institution has funds in hand amounting to \$120,000. It is expected soon to lay the corner-stone, and when that has been done an increase of the endowment fund will be easier to accomplish.

The Randall's Island Hospitals,—Dr. W. Whitehead Gilfillan has been appointed attending ophthalmic surgeon to the hospitals on Randall's Island.

Changes of Address.—Dr. Frank S. Fielder, to No. 33 West Ninety-third Street; Dr. Charles A. Ring, from Buffalo to Johnson's Creek, Niagara County, N. Y.; Dr. C. Teubner, to No. 1840 Lexington Avenue.

The Death of Dr. Alexandra Petrowa, of Sebastopol, Russia, removes one of the older of the lady physicians who entered the profession soon after the ukase went forth allowing women to study medicine in St. Petersburg. Her age was fortynine years.

The Death of Dr. Paul Diday, of Lyons, the well-known syphilographer, is announced in *Lyon médical* for January 14th as having taken place a few days before that date. He was in his eighty-third year.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 7 to January 26, 1894:

WOODRUFF, CHARLES E., Captain and Assistant Surgeon. The extension of leave of absence granted is further extended one month and twelve days.

KIEFFER, CHARLES F., First Lieutenant and Assistant Surgeon, is granted leave of absence for two months, on surgeon's certificate of disability, with permission to leave the Department of Dakota.

Moseley, Edward B., Major and Surgeon, is hereby granted leave of absence for one month on surgeon's certificate of disability.

FRICK, EUCLID B., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Keogh, Mont., and ordered to Fort Townsend, Wash., for duty at that post, relieving Ball, Robert R., Captain and Assistant Surgeon. Captain Ball, on being relieved by Lieutenant Frick, will report in person to the commanding officer, Fort Monroe, Va., for temporary duty.

Brewer, Madison M., First Lieutenant and Assistant Surgeon, will, upon the arrival of Captain Ball, be relieved from temporary duty at Fort Monroe, Va., and will return to his proper station, Fort Riley, Kansas.

Naval Intelligence,—Official List of Changes in the Medical Corps of the United States Navy for the week ending January 27, 1894.

Biddle, Clement, Surgeon. Detached from duty at the Marine Rendezvous, Philadelphia, Pa., and to wait orders. Rendezvous closed.

STONE, E. P., Passed Assistant Surgeon. Detached from the Marine Rendezvous, Boston, Mass., and to continue on special duty in Boston, Mass.

Berryhill, T. A., Passed Assistant Surgeon. Authorized to take a course of instruction at the Naval Hospital, Brooklyn, N. Y.

Browne, J. Mills, Medical Director (retired). Granted two months' leave with permission to go abroad.

Neilson, J. L., Surgeon. Detached from the Naval Medical Examining Board and ordered to the Boston Navy Yard.

Marmion, R. A., Surgeon. Detached from the Boston Navy Yard and ordered to the Smithsonian Institution.

Gravatt, C. U., Surgeon. Detached from the Smithsonian Institution and ordered to the Dale.

Green, E. H., Surgeon. Detached from the Dale and ordered to the Marblehead.

RUSSELL, A. C. II., Passed Assistant Surgeon. Ordered as a member of the Naval Medical Examining Board. Berryhlle, T. A., Passed Assistant Surgeon. Ordered to duty at the Naval Laboratory and Department of Instruction.

Babin, H. J., Surgeon. Ordered as a member of the Board of Inspection and Survey.

Du Bois, F. L., Medical Inspector, and Siegfried, C. A., Surgeon. Appointed delegates to the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Five Weeks ending January 20, 1894;

Bailhaohe, P. H., Surgeon. Detailed by the President as Delegate to the International Sanitary Conference in Paris, France. January 15, 1894.

SAWTELLE, H. W., Surgeon. Detailed as Chairman of the Board for Physical Examination of Officers, Revenue-Marine Service. January 19, 1894.

Austen, H. W., Surgeon. To represent the service at the International Medical Congress, Rome, 'Italy. (December 16, 1893.

STONER, G. W., Surgeon. Granted leave of absence for seven days. December 22, 1893,

IRWIN, FAIRFAX, Surgeon. To proceed to St. Petersburg, Russia, for duty. December 28, 1893. To proceed to Paris, France, for temporary duty. January 16, 1894.

Carter, H. W., Surgeon. To report at the Bureau for temporary duty. December 17, 1893.

Banks, C. E., Passed Assistant Surgeon. Detailed as Recorder of the Board for Physical Examination of Officers, Revenue-Marine Service. January 19, 1894.

PECKHAM, C. T., Passed Assistant Surgeon. Granted leave of absence for seven days. January 6, 1894. Granted leave of absence for six days. January 11, 1894.

GLENNAN, A. H., Passed Assistant Surgeon. Granted leave of absence for five days. December 20, 1893.

BROOKS, S. D., Passed Assistant Surgeon. To proceed to Sandusky, Obio, as Inspector. January 17, 1894.

White, J. H., Passed Assistant Surgeon. Granted leave of absence for thirteen days from December 18, 1893.

CARRINGTON, P. M., Passed Assistant Surgeon. Granted leave of absence for thirteen days from December 18, 1893.

WILLIAMS, L. L., Passed Assistant Surgeon. Granted leave of absence for fourteen days. January 17, 1894.

Bratton, W. D., Passed Assistant Surgeon. To proceed to Wilmington, N. C., for duty. January 9, 1894.

Woodward, R. M., Passed Assistant Surgeon. Granted leave of absence for ten days. December 18, 1893. Granted leave of absence for fourteen days. January 17, 1894.

STONER, J. B., Passed Assistant Surgeon. To proceed to Marshfield, Oregon, as Inspector.

Guitéras, G. M., Passed Assistant Surgeon. To proceed to New Orleans, La., for duty.

Perry, J. C., Passed Assistant Surgeon. To proceed to Norfolk, Va., for temporary duty.

Young, G. B., Assistant Surgeon. Granted leave of absence for three days. January 1, 1894.

Brown, B. W., Assistant Surgeon. Granted leave of absence for thirty days. December 16, 1893.

ROSENAU, M. J., Assistant Surgeon. To proceed to Evansville, Ind., for temporary duty. January 13, 1894.

Gardner, C. H., Assistant Surgeon. To proceed to San Francisco Quarantine for temporary duty. December 22, 1898.

Nydegger, J. A., Assistant Surgeon. Granted leave of absence for twenty-three days. December 20, 1893. OAKLEY, J. H., Assistant Surgeon. Granted leave of absence for twenty-five days. December 20, 1893.

NORMAN, SEATON, Assistant Surgeon. Granted leave of absence for thirty days. January 15, 1894.

PROCHAZKA, EMIL, Assistant Surgeon. To proceed to Louisvill, Ky., for duty. December 26, 1893.

#### Society Meetings for the Coming Week:

Monday, February 5th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private), New York; Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

Tuesday, February 6th: Medical Society of the State of New York (first day—Albany); New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburgh, N. Y., Medical Association; Hampden, Mass., District Medical Society (Springfield); Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

Wednesday, February 7th: Medical Society of the State of New York (second day); Society of the Alumni of Bellevue Hospital, New York; Harlem Medical Association of the City of New York; Medical Society of the County of Richmond (Stapleton), N. Y.; Medical Microscopical Society of Brooklyn; Bridgeport, Conn., Medical Association; Penobscot, Me., County Medical Society (Bangor).

THURSDAY, February 8th: Medical Society of the State of New York (third day); New York Laryngological Society; New York Academy of Medicine (Section in Pædiatrics); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, February 9th: Yorkville Medical Association (private), New York; Medical Society of the Town of Saugerties, N. Y.; Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn.

SATURDAY, February 10th: Obstetrical Society of Boston (private).

## Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

section in General Medicine.

Meeting of January 16, 1894.

Dr. CHARLES E. QUIMBY in the Chair.

The Value of the Hæmatocrite in the Diagnosis of Anæmia.—Dr. Juden Daland, of Philadelphia, read a paper the object of which was to point out the advantages to be gained by the hæmatocrite for ascertaining or estimating the number of red corpuscles in a given volume of blood. Those who had had experience in counting blood-cells with the hæmocytometer could recall the many hours that had been spent in the

enumeration of red and white blood-corpuscles, also the difficulties of correctly measuring, diluting, mixing, and placing in the slide the blood, and the making sure that the top cover was placed in the proper position. Few of the observers in this field but had had these same annoyances in determining the exact quantity of the diluted blood that should be placed upon the slide, and the frequency with which, even under the best of circumstances, their efforts had proved valueless, because of using either too much or too little of the diluted blood, or from the presence of foreign bodies, or from want of success in placing the top cover in position, was alluded to. Furthermore, when all these conditions had seemed to have been perfectly fulfilled, and it was believed that a perfect specimen had been secured, it was not uncommon to find, upon examining the blood, that the corpuscles were distributed unequally over the field, or, in spite of precautions, that a fine fiber from the material used in cleansing and drying the slide was present, thus making it necessary to repeat the whole process. Finally, if at last one secured a satisfactory specimen, the inaccuracies of the count were of such a character that it hardly repaid one for the hard work attendant upon the technique required in such examinations. It had been shown that no estimate was of value unless the cells in sixty-four small squares were counted, or unless, better still, two separate mounts were prepared and the cells counted in each. The eye strain, nervous excitement, and fatigue induced by three or four hours of the work were such as to make the most ardent clinical observer shrink from its too frequent repetition, particularly as the results had not been so accurate as had been hoped for. The sources of error in counting the blood-cells with the hæmocytometer were numerous. From a series of observations by the author and Dr. Carl Sadler, of Prague, they had been able to demonstrate the sources of error and also to show that they were in a great measure unavoidable. The two chief sources of difficulty seemed to be, first, inability to secure a full and thorough mixture of the blood, which was only one part of blood to ninety-nine parts of the diluting fluid, so that each drop of the mixture would contain the same number of blood-cells; secondly, to see that when the drop of diluted blood was placed upon the slide the layer of blood should represent exactly its share of the red blood corpuscles. These sources of error were most difficult to overcome. The first was in a measure obviated by prolonged shaking of the mixture, occupying three or four minutes, but the second must always remain a variable factor by the old method. In certain diseases it had been noted that the blood in the Zeiss counting pipette coagulated with unusual rapidity, and could not be thoroughly admixed. The foregoing had led the author to search for some other method of estimating the corpuscular richness of the blood. The original hæmatocrite had been found faulty in its mechanism, and also to possess a number of disadvantages. The author exhibited and described his perfected instrument. It was composed of a series of wheels so arranged that they multiplied the revolutions of an upright spindle. One revolution of the handle produced nine hundred revolutions of the frame which was placed on top of the spindle. the frame holding the tube containing the blood or fluid to be examined. After experimenting with nineteen different solutions, a two-and-a-half-per-cent. solution of potassium dichromate had been found to be the best fluid for diluting the blood. A measured quantity of blood was drawn into a tube, and an equal quantity of the solution added, and then the two were thoroughly mixed in a watch glass. The fluid was then to be introduced into a hæmatocrite tube, placed on the frame, and rotated eleven thousand times. The object was to employ a centrifugal force that would throw the corpuscles to the end of the tube. The tube was made of glass, and was graduated

with a scale that could be read off and the number of red cells readily estimated.

The blood of fifty-five healthy male adults had been examined, and the volumetric percentage found to vary between 66 and 44, the average being 515. Eight female nurses had been examined, and the maximum volume found to be 42 and the minimum 36, giving an average of 44. Most of the nurses were anomic, and it was probable that the true physiological volume was somewhat higher than the investigation had proved. The blood cells in twenty-five healthy males had been counted and compared with the volumetric percentage, and it had been found that each percentage volume represented 99,390 red corpuscles, and, as the difference was of absolutely no consequence, it became evident that each volumetric percentage was the equivalent of 100,000 red blood-corpuscles; therefore, to convert the volumetric percentage into the number of red blood-cells present, all that was necessary was to add five ciphers. In these physiological experiments it had been observed that the white corpuscles occupied a space represented by one of the lines that constituted the scale on the tube of the hæmatocrite. When such a condition as leucocytosis was present it could readily be determined, provided the number of white corpuscles exceeded 30.000 to the cubic millimetre. A prolonged series of observations had been made in the same cases to demonstrate any variability that might occur in the use of the hæmatocrite, with the result that a difference of from one to four per cent. might be expected. The author wanted it to be understood that his work was yet in the experimental stage, and that he had been rapidly working up to a point of success. It was only about a week previously that he had been able to make a step in advance by drawing the blood directly from the finger into the hæmatocrite tube and rotating it at once. By this means the greatest sources of error were obviated, those of airbubbles getting into the tube, evaporation of the fluid, gravitation of the corpuscles, and coagulation.

Dr. W. G. Thompson said that he had had no experience with the hematocrite, but he was satisfied that it had its advantages. It had seemed to him that there might arise a source of error in the ultimate results from the rapid rotation; he was not sure that it might not cause a destruction of the red cells. He would like to hear from the author of the paper on this point. The speaker's success in estimating the condition of the blood had been sufficiently satisfactory with the microscope for him not to be inclined to give up this method. Of course, he realized the sources of error that might be present, but for practical purposes he thought the results with the hemocytometer were approximately correct.

Dr. Smith exhibited an ingenious instrument for determining the amount of hamoglobin in a given case. The working of the apparatus was exceedingly simple. Its utility was commended in cases where repeated examination of the blood was required at the bedside to watch the progress of the disease.

Dr. Daland said that in regard to the number of revolutions 10,000 were sufficient to fix the volume, and this was to be regarded as a standard. In answer to Dr. Thompon's question, he said that in the dichromate solution the rotatory movement had no effect whatever upon the red cells; they were in no way injured. The red cells were thrown to the peripheral end of the tube, and the white cells did not mingle with the red, but occupied what was represented as one line on the hæmatecrite tabe. In the disease of microcytosis this condition was changed; the white cells were found to form into the red. In leucæmia the white cells formed a larger mass in the tube, the relation being, first, a layer of white cells, then one of red, then a yellowish layer, which was supposed to consist of brokendown large white corpuscles.

### Book Notices.

Supplement to the Reference Handbook of the Medical Sciences.

By Various Writers. Illustrated by Chromolithographs and
Fine Wood Engravings. Edited by Albert H. Brck. M. D.,
New York City. Vol. IX. New York: William Wood &
Co., 1898. Pp. vii-1076.

This supplementary volume is intended "to bring the Reference Handbook of the Medical Sciences fully up to date," as the preface states. It seems to us that the intention has been carried out as far as the rapid progress of medical science makes it possible to bring any such large work up to date, and the volume under consideration not only attains this end, but also greatly increases the value of the entire Handbook.

It is impossible to review in detail a book of more than a thousand pages, covering such an immense field as this one does. We are obliged to confine ourselves to a brief description of the general plan and scope. The arrangement, as in the earlier volumes, is alphabetical. There would be grave objections to this way of grouping the various articles were it not for the fact that a very complete index makes it easy to find all that is said upon any topic, no matter what may be the title of the article or articles in which it is mentioned. This index gives both the subjects and the names of the writers who have contributed articles.

The book is not intended to give exhaustive essays upon everything connected with the science of medicine; it is meant to be a useful compendium for the practical working men of the profession. A large part of it is devoted to therapeutics, dealing specially with the newer remedies, and the facts about the latter are presented in a clear and satisfactory way. The details of technique in modern aseptic surgical procedure are also well presented. The article upon Bacteriological Technology is worthy of particular praise, as is also that upon Histological Formulæ. The article upon Diphtheria is very good, and gives due weight to the importance, diagnostically considered, of the Loefler bacillus. Much valuable information is given about hygienic matters and disinfection. Among the articles of a more theoretical kind, those on Heredity and allied topics deserve mention. In view of the interest now taken in the thyreoid, the papers on its anatomy, pathology, etc., will prove interesting as well as important.

Of course, there is much difference in the worth of the various articles—it could not be otherwise, since the writers number upward of a hundred and twenty. It is but just to say that, on the whole, the standard is high and the entire work is a credit to its publishers, its contributors, and, above all, its editor,

The presswork is good. Most of the illustrations are very well done, and a sufficient number of them are inserted to make clear matters which without them would be obscure.

Die Kolonisierung der Geisteskranken in Verbindung mit den Offen-Thür-System, ihre historische Entwickelung und die Art ihrer Ausführung auf Rittergut Alt-Scherbi z. Von Dr. Albrecht Paetz, Sanitätsrath, Direktor der Provinzial Irren-Anstalt Rittergut Alt Scherbitz, etc. Berlin: Julius Springer, 1893. Pp. x-242.

As is indicated by the title of this book, the colony system and open door system of earing for the insane are here advocated by the author, who is the medical superintendent of the model colony for the insane of the world—viz., Alt Scherbitz, near Leipsic. This colony has become especially well known through Mr. Letchworth's book, The Insane in Foreign Countries, and also through the descriptions of several American phy-

sicians who have visited it. In the work of Dr. Paetz we have, first, a chapter upon the development of insane asylums from prehistorical times to the present day, and our numerous latter-day methods of construction and arrangement are described, such as special curative institutions, mixed asylums, the pavilion system, and so on. Then follow chapters upon the agricultural colonization schemes carried out in France, Germany, and Bohemia, with the advantages and disadvantages clearly set forth. The rest of the book is given up to the description of the plan followed at Alt-Scherbitz, which is not fully colonial, but a combination of the asylum and colonization systems. Alt-Scherbitz, to a visitor, looks like a small suburban village, and has nothing to suggest an institution about it, much less an insane asylum. The volume is richly illustrated with map, plans, and photo-lithographs. No asylum in this country can afford to be without it, for a standard of excellence in the care of the insane such as is set forth in this book should be ever before the eves of both asvlum superintendents and asylum managers, in order that some day we may make an approach to a reasonable and humane method of caring for the insane.

Text-book of Normal Histology: including an Account of the Development of the Tissues and of the Organs. By George A. Piersol, M. D., Professor of Anatomy in the University of Pennsylvania. With Four Hundred and Nine Illustrations, of which Three Hundred and Fifty-eight are from Original Drawings by the Author. Philadelphia: J. B. Lippincott Company, 1893. Pp. xviii-11 to 439. [Price, §3.50.]

The author's practical experience as a teacher has been of great use to him in indicating what a text-book of histology should teach and what it should omit. He states that he has endeavored to steer between the Soylla of too great conciseness of statement and the Charybdis of too great elaboration of detail, and his successful efforts in this direction have resulted in the production of what is one of the best text books on this subject that we have.

The salient feature of the volume is the constant aim to impress upon the mind of the reader the necessity of recognizing the underlying morphological relations of the tissues. The wider bearing of this relationship becomes apparent in the account of the histological differentiation concerned in the development of the tissues and the organs. The general work of the volume is excellently done.

The author has been at great pains to provide suitable illustrations, having made many of the drawings himself with the aid of the camera lucida or the photomicroscope. In these cuts the natural appearance of the preparations is well preserved.

The volume is entitled to and undoubtedly will receive, a cordial welcome from the profession.

A Text-book of Physiology. By M. Foster, M. A., M. D., LL. D., F. R. S., Professor of Physiology in the University of Cambridge and Fellow of Trinity College, Cambridge. Fifth American, from the Fifth English Edition; thorough ly revised, with Notes, Additions, and Three Hundred and Sixteen Illustrations. Philadelphia: Lea Brothers & Co., 1893. [Price, \$4.50.]

This new American edition of this well-known text book contains all the additions and corrections of the fifth English edition, the separate parts of which were reviewed in these columns as they appeared from time to time. The present volume is printed and illustrated in the excellent manner that characterized its predecessors, and that the entire work is con-

tained in one volume makes it much more convenient for stu-

Surgery. A Manual for Students and Practitioners. By Bern B. Gallauder, M. D., and Charles N. Dixon Jones, B. S., M. D. Philadelphia: Lea Brothers & Co. [Price, \$1.75.] [The Students' Quiz Series.]

THERE are many works on surgery of far greater pretensions than this little volume that are likely to be less useful. The authors have been very successful in keeping their material within a most reasonable limit, and in doing so they have not sacrificed lucidity. The work is illustrated with well-selected cuts, and we believe it will be popular with students.

The Principles and Practice of Surgery. By John Ashiderst Jr., M. D., Barton Professor of Surgery and Professor of Clinical Surgery in the University of Pennsylvania, etc. Sixth Edition, enlarged and thoroughly revised. With a Colored Plate and Six Hundred and Fifty-six Illustrations in the Text. Philadelphia: Lea Brothers & Co., 1893. Pp. xxviii-33 to 1166. [Price, \$6.]

THE sixth edition of this standard work has been so thoroughly and efficiently revised that it is almost a new work.

One of the first additions to the volume is the chapter on surgical bacteriology, by Dr. C. B. Nancrede, who has presented this subject in a clear, logical, and concise fashion. In the plate illustrating some micro-organisms it might have been well to specify the amplification of each organism.

In the treatment of cicatrices following burns no mention is made of the use of Thiersch's skin-grafting method, that is more likely to be available than twisting or sliding flaps of sound skin. In fact, insufficient prominence is given to the extensive field of usefulness of this method of grafting.

The author still holds his conservative position regarding the advantages of cerebral localization and the cases in which recourse to cerebral surgery is justifiable.

So, also, he says regarding the surgery of the spine: "Considering, therefore, the not infrequent favorable issue of these cases (fracture of the spine) under expectant treatment, nearly twenty-nine per cent, having received benefit, and only sixty-nine per cent. dying of all cases taken together, we are surely justified in declaring that trephining of the spine, if ever resorted to, should be reserved for very exceptional cases."

Dr. Hirst has revised the chapter on gynæcology, Dr. de Schweinitz that on diseases of the eye, and Dr. Randall that on diseases of the ear.

The revision has added some twenty pages to the book as well as a number of new illustrations.

The volume sustains its position as a safe and conservative guide for the student and the practitioner.

The Navrative of a Busy Life. An Autobiography. By AR-THUE HILL HASSALL, M. D. Lond., Member of the Royal College of Physicians of London, etc. London: Longmans, Green, & Co., 1893. Pp. iii-82.

One can not but say, on reading this volume, that it is indeed the narrative of a busy life. The grandson and son of a physician, Dr. Hassall was born in 1817. His early education was limited on account of lack of funds, and this same necessity seriously hampered his course while a medical student. During that portion of his career he paid great attention to the study of natural history, and the habits of observation thus acquired undoubtedly stimulated his future lines of investigation.

In 1839 he became a member of the Royal College of Surgeons and in 1841 of the Apothecaries' Company.

In the first portion of his professional career he assisted a brother, who was also a physician, and found time during his professional pursuits to make an investigation of the fresh-water Algo and of Fami.

Dr. Hassall afterward left his brother and began practice in a suburb of London. While thus engaged he published several memoirs on sanitary topics, and conducted in behalf of the Lancet an investigation on the adulteration of food.

In 1852 his well-known work on *The Microscopic Anatomy of the Human Body* was published. The author's subsequent career was full of work until, in 1866, a serious pulmonary hæmorrhage required the cessation of work and a change of his residence to Ventnor. While he was there his activity manifested itself by planning and creating the National Hospital for Consumption.

Subsequently Dr. Hassall went to San Remo, where he has since resided. He tells the story of his life in a pleasant fashion, and it contains many suggestions that may be useful to those about to enter on their professional career.

Modern Gynacology. A Treatise on Diseases of Women, comprising the Results of the Latest Investigations and Treatment of this Branch of Medical Science. By Charles He Визноме, M. D., Assistant Gynacologist to the Demilt Dispensary, etc. Illustrated. New York: E. B. Treat, 1893. [Price, \$2.75.]

The author considers that the majority of the text-books on diseases of women are written from the standpoint of the specialist, and are likely to be too voluminous for the use of the general practitioner, who should be competent to give advice regarding gynæcological subjects. Accordingly, it is the effort of this book to place before the physician a clear, commonsense statement of the symptoms of the various diseases of the female sexual organs and to indicate in detail the methods of treatment that can be applied by him, and also the methods requiring the aid of a specially trained consultant of larger experience. The author's style is clear and he has described the various features of routine gynæcological work in a practical manner.

Healthy Hospitals: Observations on Some Points connected with Hospital Construction. By Sir Douglas Galton, late Royal Engineers, K. C. B., Hon. D. C. L., LL. D., F. R. S., etc. With Illustrations. London: H. K. Lewis, 1893. Pp. xi-287.

The author states that the principles enumerated in this book are not new, but they lie scattered through various publications, and it has been his object to bring them together and, by showing what points are essential to health in hospital construction, to enable those upon whom the regulation of the construction devolves to concentrate expenditure upon these matters shone. He hopes to prevent the erection of large, palatial hospitals in towns or other localities that are unsuited to them, for simplicity of design and of detail that aims to provide abundance of light, air, and easily cleansed surfaces is more important than skill in architectural design.

The various chapters define what a hospital is, where it is best situated, the conditions that vitiate the air in an occupied room, and the quantity of air necessary to nitigate these conditions, the purification of air, the movement of air, the methods of warming and lighting, the ward unit and its essential features, and the construction and arrangement of special hospitals.

Each year witnesses the construction of new hospitals throughout the country, and medical as well as lay members of hospital boards will find this volume useful and suggestive.

Myxedema: and the Effects of Climate on the Disease. By A.
 MARIUS WILSON, M. D., B. S. Durb., L. R. C. P. Lond., M. R.
 C. S. Eng. London: The Scientific Press, Limited, 1894.
 Pp. 9 to 36. [Price, 2 shillings.]

In this brochure the author reviews the history of myxœdema, its ætiology, symptoms, pathology, diagnosis, prognosis, and treatment. He considers that the disease may occur in any climate. The book is a fair, but not comprehensive, résumé of our knowledge of this interesting condition.

Manual of Physical Diagnosis. For the Use of Students and Physicians. By James Tyson, M. D., Professor of Clinical Medicine in the University of Pennsylvania, etc. Second Edition, revised and enlarged. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xi-9 to 241. [Price, \$1.50.]

It would seem that a work with such a title limited to palpation, percussion, and auscultation of the thorax and abdomen was somewhat circumscribed in scope. We should expect some reference to the general methods of examination of the eyes, ears, nose, mouth, and throat. So far as the examination of the lungs and heart is concerned, the work is quite satisfactory, but it is far from being a manual of physical diagnosis.

Outline of Physical Diagnosis of the Thorax. By ARTHUR M. CORWIN, A. M., M. D., Demonstrator of Physical Diagnosis in Rush Medical College, etc. Chicago: The W. T. Keener Company, 1893. Pp. viii-9 to 111.

This little volume presents in a concise tabulated form the essential features of the physical diagnosis of the thorax. It will undoubtedly prove to be very useful to the student in the clinical study of thoracic auscultation and percussion.

A Handbook of Ophthalmic Science and Practice. By Henry E. Juler, F. R. C. S., Ophthalmic Surgeon to St. Mary's Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital, etc. With Illustrations. Second Edition. Philadelphia: Lea Brothers & Co., 1893. Pp. xvi-549.

THE first edition of this work won a high place in the regard of students of ophthalmology, because of its having the points they wished to look up stated concisely yet clearly and with sufficient fullness. In this second edition considerable alterations have been made in both the text and the illustrations, and the credit won by the first has been well maintained. The chapters on refraction show evidence of great care in their preparation, but the description of the Javal-Schiotz ophthalmometer shows how difficult it is to keep a text-book abreast of the times. The improved form of this instrument, which has for the last few years proved so valuable an adjunct to our armamentarium, is not mentioned, and the original pattern is described rather as a curiosity than anything else. But such faults are of omission and are to be excused, because the author of such a work has to grapple with the very serious question of what to omit in order to make it of a reasonable size.

Typographically, the book is excellent. It is printed on good paper and the cuts are clear and distinct.

Baden-Baden und seine Thermen. Von Dr. med. W. HENRY GILBERT, Hausarzt des Sanitoriums und Kurarzt in Baden-Baden. Wien und Leipzig: Wilhelm Braumüller, 1893. [Braumüller's Bade-Bibliotheke. Pp. viii-169.] [Preis, M. 2 50.]

This handbook of Baden-Baden gives a satisfactory review of the history, topography, and various features of this resort, as well as a compreliensive description of the springs, their physiological action in disease, and the various diseases for which their waters are recommended. The author's familiarity with these springs makes the work authoritative.

Mental Nursing, or Lectures for Asylum Attendants. By Wil-LIAM HARDING, M. B. (Ed.), M. R. C. P. (Lond.), Assistant Medical Officer, Female Department, Berrywood, Northampton, etc. London: The Scientific Press, Limited, 1893. Pp. vii-131. [Price, 2s. 6d.]

WE should object to the title of this book, for mental nursing might be applied as well to a kindergarten as to an insane asylum, and possibly even more appropriately. As indicated by the subtitle, it consists of lectures for asylum attendants. There have been several similar primers issued, and this takes its place among the best of them, although possibly the nurses in American hospitals for the insane could study Dr. Granger's little book with more advantage.

La pratique des maladies du système nerreux dans les hôpitaux de Paris. Aide-mémoire et formulaire de thérapeutique appliquée. Par le Professeur Paul Lefert. Paris: J. B. Baillière et fils. Pp. 8-9 to 285. [Prix, 3 fr.]

A USEFUL little pocket handbook giving the therapeutic measures resorted to in Paris hospitals in the treatment of nervous diseases. The diseases are arranged alphabetically, and under each heading various professors-Charcot, Babinski, Huchard, Potain, Lancereaux, Laveran, Falret, Peter, Marie, and others-briefly describe their remedies and procedures. As French methods of treatment differ very much in important particulars from our own, the book is interesting and profitable reading.

#### BOOKS, ETC., RECEIVED.

A Clinical Text-book of Medical Diagnosis for Physicians and Students, based on the most Recent Methods of Examination. By Oswald Vierordt, M. D., Professor of Medicine at the University of Heidelberg, etc. Authorized Translation, with Additions. By Francis H. Stuart, A. M., M. D., Member of the Medical Society of the County of Kings, New York, etc. Third Revised Edition. With One Hundred and Seventy-eight Illustrations, many of which are in Colors. Philadelphia: W. B. Saunders, 1894. Pp. xv-700. [Price, \$4.]

Lectures on the Surgical Disorders of the Urinary Organs. By Reginald Harrison, F. R. C. S. Fourth Edition, rewritten. London: J. & A. Churchill, 1893. Pp. xvi-588.

The Use of Antiseptics in Midwifery; their Value and Practical Application. By Robert Boxall, M. D. Cantab., M. R. C. P. Lond., Assistant Obstetric Physician to and Lecturer on Practical Midwifery at the Middlesex Hospital, etc. London: H. K. Lewis, 1894. Pp. 35. [Price, 1s.]

Transactions of the American Association of Obstetricians and Gynæcologists. Vol. VI. For the Year 1893. Philadelphia: William J. Dornan, 1894. Pp. viii-4 to 308.

The Necessity for Special Institutions for the Consumptive Poor. The First Step toward the Complete Eradication of Tuberculosis. By H. Longstreet Taylor, A. M., M. D., St. Paul. [Reprinted from the Northwestern Lancet.]

The Modern Eye; with an Analysis of Thirteen Hundred Errors of Refraction. By W. F. Southard, A. M., M. D. [Reprinted from the Pacific Medical Journal.]

The Treatment of Diphtheria. By F. E. Waxham, M. D., Denver. [Reprinted from the Journal of the American Medical Association.

New York State Reformatory. Report of the Board of Managers to the Legislature. For the Year ending September 30, 1893.

## Miscellann.

Nostrum Advertisements and the Journal of the American Medical Association .- The following letter from Dr. Solomon Solis-Cohen, of Philadelphia, was published, "by order of the trustees," in the Journal of the American Medical Association for January 20th:

About a month ago I addressed you a letter replying to one of your editorial articles. As that letter has not yet been printed, and as I have not heard further in reply to my query concerning it than that search would be made, I presume it has been lost, and I therefore beg to again communicate its substance, in the hope that it will receive an early insertion, together with this preface explanatory of its apparent tardiness. I wrote at first and again write because I desire to see the Journal a perfect representative of the best in American medi-

In your editorial you animadverted on the fact that some of your Eastern contemporaries "lectured" the Journal on the sale of its advertising columns to nostrums, and you replied that (1) there was an attempt to make a difference between a "physicians' journal" and a "publishers' journal," which you thought unfair, and (2) that no one had ventured to explicitly name the objectionable advertisements.

At this lapse of time I have had to repeat your argument as above in order to make my answer intelligible.

While I have no concern in the question between you and your contemporaries as to which is "pot" and which "kettle," and whether or not the etiquette that should prevail among culinary utensils has been violated by cries of "Blacky" from a soot-covered vessel, I have very much concern with the main issue, and on it I beg to respectfully differ with you in both your contentions.

1. Is a "physicians' journal" bound by more stringent rules than a "publishers' journal?"

Let me answer this by an apt illustration: At the time I brought to the attention of the Philadelphia County Medical Society the question of nostrum advertising in medical journals I had some correspondence on the subject with a friend, an honorable gentleman, a member of a well-known publishing house. His answer to my request that his house should decline nostrum advertising was about as follows: "So long as the journal of which you are part owner sets the example of receiving such advertisements you have no grounds on which to criticise us. When the Journal of the American Medical Association declines to advertise secret preparations we will likewise take the matter into consideration."

So you see there is a very important difference between a "physicians' journal" and a "publishers' journal." I am "part owner," to quote my friend, and every other member of the American Medical Association is likewise "part owner" of a journal which persists in a course of conduct that we believe to be wrong and that we seek to prevent in others. Our reform must "begin at home."

But even if this argument were not so forcible, there is one that you have persistently ignored. The Code of Ethics, which is not yet repealed, and which will not, I trust, be repealed, prohibits not only the use of nostrums by physicians, but any action that tends to increase their use. Surely advertising them "tends to increase their use!" Were it otherwise, the "enterprising proprietors" would not waste their money on advertisements.

Furthermore, even if you ignore this special provision of the Code, there is the resolution adopted at the instance of the Medical Society of the State of Pennsylvania at the Detroit meeting of the American Medical Association which expressly forbids the trustees of the *Journal* from advertising secret preparations.

The ingenious evasion by which the trustees have sought to nullify this resolution, and which they must be aware is only laughed at by intelligent men, does more credit to their acuteness than to their straightforwardness. Nor does the fact that their action was passed over in silence at the Milwankee meeting render it any the less blameworthy. The fact apparently is that the trustees have deliberately decided to disobey not only the spirit but the letter of the Code and of the Detroit resolution. They do not even "keep the word of promise to the ear, to break it to the hope," but break it to ear and hope alike. On the surface, their action seems to highly deserve a vote of censure: I will be very glad to learn that there is some justification for it not apparent. If it be said that without the money received for this prostitution the Journal could not exist, it would be very difficult to answer such a plea in respectful terms. I have no doubt that you can elicit a similar plea from nearly every strumpet. We can pity the strumpet, but surely the Journal does not wish to be an object of pity!

2. Has no one explicitly pointed out the objectionable advertisements?

A number of them were mentioned in my paper before the Philadelphia County Medical Society, Shall Physicians become Sales Agents for Patent Medicines? which was reprinted in the Journal and editorially commented upon. The Pittsburgh Medical Review has frequently named them. In my letter mislaid by you I ventured to give you another list. In this communication I will content myself with naming only one—the one which is very properly headed An Affront to the Medical Profession. But you need no other rule than that of the Code—which makes secreey the sign and test of a nostrum.

The Intravenous Injection of Saline Fluid,—In a minor editorial article the Lancet for January 13th says:

There can be little doubt that the injection of salt solution into the veins constitutes a valuable addition to our therapeutic measures in certain otherwise hopeless cases. We refer more especially to cases of severe accidental or unavoidable hæmorrhage, to severe cases of post-partum hæmorrhage, as well as to cases of extra uterine pregnancy where there has been rupture of the sac with profuse intraperitoneal hemorrhage. It would seem that the injection is also indicated in some cases of severe operation where a large quantity of blood has been lost, but less than is needed to prove immediately fatal. In a certain proportion of such cases, although the patient is not pulseless at the end of the operation, death occurs before many hours have elapsed, apparently from secondary syncope. In some cases of the kind, at all events, it appears probable that the injection of salt solution may avert an unfavorable termination. It is certainly a great step in advance to have it established that the injection of actual blood is unnecessary; for so long as blood was thought to be required the practical difficulties surrounding the procedure were so great that it has but rarely been employed; and it is, in the light of our present knowledge, as certain as anything can well be that many lives have been lost solely for the want of some ready means of restoring the volume of the circulating fluid. It is evidently of great importance that the method should be a simple one, and especially that it should not involve the possession of some more or less complex apparatus which the ordinary practitioner could not be expected to have at hand. As regards the fluid to be used, the simplest of all-plain water-will do, since successful cases are reported in which water only has been injected; but it is certainly preferable to use a solution of common

salt, the proper strength being a teaspoonful of the latter to a pint of water. Here again, while it is no doubt desirable, if circumstances permit, that the solution should be sterilized, it is abundantly clear that it is by no means absolutely essential. A patient should not be allowed to die from loss of blood, where it is practically certain if let alone she would do so, merely on account of an extremely remote risk of septic poisoning from the water in the kitchen kettle and the salt in the table salt cellar. Then as to the quantity of fluid to be injected. This should depend upon the amount of blood that has been lost, but this often can not be accurately estimated. It is important to note, however, that a few ounces are of little or no use. In cases really requiring this treatment it is a question of injecting pints. From a minimum of two pints in the less severe cases to a maximum of six pints in the worst cases is the amount of salt solution to be used. This should be continued till the pulse can be felt at the wrist. Opinions differ as to the rate at which the fluid should be injected; some consider that a pint in four minutes is not too fast, while others think that the rate of injection should be a third of this, or less. Probably the actual state of depletion of the circulation causes the rate at which the injection may be safely made to vary in different cases. The temperature of the fluid-used should be about the same as that of the body. The actual apparatus required consists only of a cannula and a few feet of India rubber tubing connected with a vessel to hold the salt solution. The form of the vessel is immaterial; indeed, the tubing, converted into a siphon, may be made to convey the fluid from an ordinary jug. Now that the whole procedure has been so much simplified, we may expect to hear of it being more frequently resorted to in the coming year. Certainly no patient should be allowed to die from hæmorrhage without an attempt being made to save her by means of the intravenous injection of salt solution.

An Ovarian Mamma,-In an abstract of an article in the Melical Press and Circular the Quarterly Medical Journal for Yorkshire and Adjoining Counties says that Mr. Bland Sutton, in the course of an abdominal section upon a woman, aged twenty-six, who had been admitted into the Middlesex Hospital suffering from what was supposed to be peritonitis, opened into a cyst which proved to be dermoid in its nature, and on the wall of which, when the contents of the cavity had been cleared out, he discovered a well-formed ovarian mamma, presenting the usual characteristics of that gland in the virgin. It was somewhat larger than a tangerine orange, had a wellformed nipple, but no areola, and was composed of fat in the center of which was a cluster of glandular material the ducts of which traversed the nipple. In the course of his remarks made at the time Mr. Sutton pointed out that this special form of abnormity was, comparatively speaking, rare, as in his own experience he had only met with three examples of it. Nipplelike and mammary projections in which no glandular structure is present are of frequent occurrence. The patient made an excellent recovery.

Modern Medical Journalism was the title of a presidential address delivered by Mr. J. Greig Smith, professor of surgery in University College, Bristol, England, before the Bristol Medicochirurgical Society on October 11th, and published in the December number of the Bristol Medico-chirurgical Journal. In the course of his address Mr. Smith said:

Modern journalism has certain characteristics which are peculiar to our age and time. This is the age of the reporter, not of the scholar. The material of literature is news, not thought; gossip, not work. The chatter of the newsmonger pushes aside the matured thought of the man of letters. We are deluged with a shallow flood of literature, and we are so

occupied in paddling about in its smooth and tepid pools that we scarcely care to try our strength in the rougher and colder waters of deep thinking.

This is also the age of advertisement. The desire of the writer is rather to be widely read than to write well. The unavowed aim of the writer is the avowed aim of the journal-a wide circulation; and the purpose of this wideness of circulation is not that knowledge may be diffused, but that advertisements may be caught-and money. Unknown men write to advertise themselves; known men are induced to write to advertise the journal. The chief end of journalism is to catch advertisements; the trail of the advertiser is over all.

Now, the population of these islands being, on good authority, mostly fools, the editor who hopes to secure the largest number of readers-the widest circulation-must cater accordingly. And so the successful editor does. The writing is not up to the highest intelligence, but down to the meanest capacity. The leveling is down-down to the dead level of the school board. Free education, wide circulation, and cheapness -cheapness in every sense-go well together. They are the Fates-I had almost said the Furies-of modern journalism.

And now the advertiser is turning on us. He is already the mainstay of the press; naturally he seeks to become the arbiter of letters. It is openly stated that he now dictates to the editor what authors shall write for his paper. If a story by a certain popular author is not in the magazine, so increasing its circulation, the advertiser will withdraw his advertisement. It is whispered even that the review of a book or a report on manufactures may vary directly as the square of the inches occupied in advertising them. This is a sad fact for literature; but it is a fact, and we must face it. I confess that I should like to fight it.

Now, is there anything of this sort in modern medical journalism? I should like to put to the modern medical editor one test question, and let his answer decide. I should ask: "Which would you consider the better copy for your journalthe clever gossip of a keen reporter hanging around the deathbed of an emperor, or the most scientific paper ever written on cancer of the larynx?" I know what his answer would be, and so do you.

There are sundry difficulties which meet the best-intentioned editor which he can not remove, and which he must accept. One of these, I grieve to say, relates to the deficient literary education of the average medical man. For some mysterious reason the art and science of logic is not expected to be known by medical men. It is not known, and their writings show it. The arts of rhetoric and composition also are ignored; even the humdrum rules of grammar are in abeyance. How much of the editor's function is the humble one of correcting a school exercise in grammar and composition the editor only knows. It is certainly much more than it ought to be, and much more than it need be, if those who guard the portals of medical education were to give some heed to the outery of those who practice their profession and teach it.

This, then, to begin with. We must accept the fact that with a few, a very few, and sometimes brilliant exceptions, the literature of medicine at the present day is, as pure literature, either indifferent or positively bad. Scarcely a single issue of a journal is without a paper from which a man educated in ordinary literary methods could not extract abundant examples of errors in logic, in rhetoric, in composition, and even in hum. ble grammar.

Another fact which the editor must accept is the widespread ignorance of the history of medicine-recent and remote -which his contributors display. Such ignorance, betraying

who hold that it is only by courtesy that our profession is called "learned"; that we are educated by rote, and not by thought; that the evolution of ideas has no interest for us; and that our classics being dead, may as well be buried. There is ignorance not only of classics, but even of class books. It would truly seem as if knowledge in our profession began to decay after five years, and was buried and forgotten after ten. However this may be, it is certain that too many writers show a culpable ignorance of, or neglect of, the works of others in the fields they seek to cultivate.

From this condemnation I desire to exclude the literature of our American brethren. The country which has given to us the Index Medicus and the Index Catalogue of its splendid library is not likely to fail in knowledge of the history of medicine. A knowledge of the work of others that is nearly always honest and thorough is as common in the best American medical literature as it is rare in our English journals. The man who writes on his own experience and knowledge writes on a poor and narrow and shifty foundation. In science he is to be found only in medicine; and in scientific medicine he bears the prefix—in all its significations—British.

It used to be true that the weight of the printed word was greater than of the spoken. We have changed all that. News is news none the less that it is either folly or lies: perhaps it circulates all the better. In past times also the printing of a book cost much money. Necessity, then, if nothing else, made a man think much before printing his thoughts. The value that a man put on the products of his brains was testified to by the finish of the garb in which he clothed them. It would be easy to put before you a score of books printed from a half to a whole century ago, and say of each of them that, in respect of printing, paper, binding, and more especially of illustrations, we never see their like now. The artistic finish then sought after is now replaced by the blurred mimicries of the "process block." And if we do borrow, as we frequently do, from the illustrations made by our predecessors, we treat them as time does their tombstones, by defacing their surfaces and roughening their lines; but not as time does, by making them venerable. What would a Cooper, or a Bell, or a Miller, or a Liston, or a Fergusson be not justified in saying of the successive generations of bookmakers who have borrowed their engravings and reproduced and defaced them?

And all that can be said in favor of our modern methods of illustration is that they are cheap. Certainly they are cheap.

And our journals! Look at those piles on our tables! Of the thousands and thousands of papers in them how many are worth preserving? how many are worth reading? how many are worth only cursing? The dew of knowledge! Medical knowledge is not a dew, but a deluge. It drowns rather than nourishes.

The man who earnestly and honestly seeks to keep abreast of real knowledge has to educate himself in a course of training in values whereby he finds out and knows the fool, and the drudge, and the bore, and the advertiser, and learns to avoid them. When he has done this, he finds that his labors are not so hard after all. It is, then, a mere turning over of thousands of leaves and a close reading of tens of pages. But it takes a long time, and greatly tries one's patience, to learn whom to avoid in medical literature.

And here our editors might help us. They might select for us. They might silence the chatterer and make the worker talk. You can scarcely put too cruel a gag on the garrulous. They are doubly mischievous, for not only do they waste the reading energies of their brethren, but they oust the work of men worth reading. It may be that the man who bustles about itself on every hand, lends color to the views of certain cynics I in the van of progress, seeming to do much but really doing

nothing, like the Handy Andy of the circus, pleases the audience; and that may be why the editor supports him. But let us be careful lest the genuine actor in his dignity and pride, not caring to play to the gallery, and not asked to play to the stalls, wait outside altogether, or even retire to his tent and sulk.

The best men and the best workers are silent and retiring; the editor must seek them out, and drag them out, and make them speak. This is no easy matter, as I can from experience testify. It is very hard to get our best men to write. One of my failures I specially deplore, for the man whom I tried to persuade is now, to the great loss of the West of England, no more with us. I refer to the late William Liddon, of Taunton. His last promise to write for our Journal was given me between three and five one beautiful morning when we were driving over the Quantocks. I scarcely knew which most to admire: his vivid appreciation and description of a lovely sunrise then going on, or his exquisitely clear, almost photographic, language in describing our case and others in his experience that bore on it. He promised to write for our Journal; he might have done it; he can not now. It is a loss to our art that the work of such men as Liddon lives only in the memories of friends and patients. It would be a gain if our editors were to insist on its being kept alive.

An equally great blessing would be to find some editors who, in respect of certain well-recognized classes of papers, would insist on their entombment.

There is the paper of the pushing clinician. We are warned of its appearance by a leaderette, which informs us that "at 1.30 on the afternoon of Tuesday, at the South London Hospital, Mr. Hepaticus Brown removed both suprarenals for Addison's disease. We are promised full particulars for a future number." The anxiously-awaited particulars appear a mouth later as a paper On Removal of the Suprarenals for Addison's Disease: a successful case, with a complete list of all other operations. Hereafter Mr. Hepaticus Brown poses as the leading authority on diseases of the suprarenals. This path to high repute is much affected: it is easy and broad, if it is not very straight.

Then there is the pushing scientist. We, his teachers and examiners, probably knew him as a gentle, plodding young man with a great capacity for note-taking. Now, with the help of a scholarship, asked for and granted, he has started hotly in pursuit of something called Research (spelled with a capital letter). He tells us everything he sees in the new path, and he sees much that is wonderful. If such men could be made to hold their tongues until they had spent some years as hewers of wood and drawers of water in the workshops of our masters in research, the world might be richer; it certainly would be none the poorer.

Then, once more, there is the pushing practitioner. His pride is puffed up and his reputation is increased by a systematic publication of all his wonderful cases. As we know, wonderful cases are found in greatest numbers by the youngest men in the smallest practices. Our pushing practitioner has not long left the schools; and he believes that science and art have stood still there since he left them. An editor who would give to such men the answer that the old lady gave to her pushing grandson when he sought to explain to her the philosophy of sucking eggs would be a gain to medical journalism.

And so on. It is weary work classifying the bores and the fools; and it would be wearier work crushing them. We are a polite people, we practitioners of medicine. Soothing the bodily pangs of suffering humanity seems to beget in us a scatimental horror of hurting the mental feelings of our worrying brethren. But let us not overdo it. Too much salaaming may make the spine too flexible; and we want backbone. To stand up square-

ly and strongly against all these abuses: to fight them and to crush them—who shall do it? It must be done if we seek to rise to higher levels. How are we to do it?

Here are our motives: to push aside the chatterer; to make the worker speak; to bring measures to the front, not men; to eschew all appearance of artificial advertisement, either for measures or for men; to let both measures and men rest on real merit; to speak the truth, and nothing but the truth, of men, of books, of papers, and of work; and throughout to have our purveyor of intellectual food like the high-class purveyor of material food, not only stand at the door and personally see that nothing inferior or unwholesome is distributed from his establishment, but also actively go out and seek for the best procurable pabulum for his customers. Such a man will not only stimulate the producer to surpass himself in invention; he will also crush out the incompetent and the careless. He is greatly wanted in our literary world.

May we hope for a higher medical journalism in these islands? Shall we ever see a journal in which every page records good work by capable workers, and every sentiment bespeaks honest thought by vigorous minds? Or must it be our doom all our lives, seeking for the grain of wheat, to have to hunt through those heaps of journalistic chaff?

I expect no more than has been. I will speak only of my own department of practice-surgery-and I will quote as an instance the Transactions of the Royal Academy of Surgeons of Paris as they appeared a hundred and more years ago. If all the societies, and all the associations, and all the colleges of all the English-speaking medical men (and women) in Europe, Asia, Africa, and America were at the end of the nipeteenth century to give to the world a few such volumes as these few workers in France gave it at the end of the eighteenth century, I should be content. After a hundred years, with all our opportunities, we have seen no such work as this-so good, so abiding, so thorough. Why is this? Is it that the standard being lower the whole work suffers? The standard must be low when it is in effect the voice of the multitude, the behest of a "wide circulation." Are we, then, with our claims and our motives, to work down to this standard? or shall we not rather seek to create a higher standard—a standard with no upward limit, but with a very decided lower one? Shall we ask our brethren to raise their intellects to our literature; or shall we continue to make our literature easy for our brethren's brains?

Literature made easy is literature easily made. Journals are numerous, pages must be filled, and writing must be encouraged. On the same platform, with the same audience and for the same time, any one man may talk as long as any other. In order that he who runs may read, it would seem as if the writing were done running. All may write; all may speak; and all must read, and listen. Surely our medical republic of letters is the freest and openest of all. If letters could keep wisdom alive, surely we are the people and wisdom will die with us.

A Case of Non-penetrating Gunshot Wound of the Heart.—In the Nouveau Montpellier médical for January 6th there is an article contributed by Dr. S. Morer, of which the following is the substance: On the 11th of October he had been called upon to examine a woman who had been shot in the chest three days before. She was breathing heavily and complained of a pain in the anterior region of the chest. A small wound, three millimetres in diameter, was found on the right side of the sternum, a little to the outer side of the median line at the level of the sternal insertion of the fourth rib. This wound, which was black-looking and surrounded with dried blood, gave issue to a little stream of black blood. This stream felt in a slight degree the action of respiration, but was not mingled

with air, and there was no wheezing sound such as follows the entrance of air into the thorax.

At the time of the shooting the woman did not lose consciousness, but felt a terrible pain and oppression. The wound was still bleeding, although the flow of blood was greatly diminished. The patient had made a long journey to appear before a judge, and was so weak that her entrance into a hospital was ordered, where she was at once examined. The examination of the chest showed a slightly accelerated action of the heart, but without any abnormal modifications. The patient complained of an intense præcordial pain, the cardiac dullness was somewhat increased, the circulation was bad, and the face and the nails were very slightly cyanosed. The lungs and the pleura did not show any lesion, but the respiration was very much accelerated. A probe was introduced with all necessary precaution into the wound, and touched a hard substance which gave a metallic sound and seemed to be imbedded in the middle of the sternum, at which point the probe was stopped at a depth of a little less than a centimetre. A small incision showed nothing but fine splinters of the sternum. Under those circumstances the wound was closed with a dressing of collodion and iodoform, thus making an exact occlusion, and over that a dressing of cotton. This was done after the wound had been washed with antiseptics. The patient was pregnant and very near the time of her confinement. Owing to objections on the part of the woman, an examination as to the state of the nterus was impossible, but the child was alive and its movements were perceived on several occasions. Bouillon, coffee, and antispasmodics were prescribed.

On the 12th of October the temperature in the morning was 98°2° F., and the patient complained of severe pains in the abdomen, but she refused to allow any examination to be made. In spite of the careful dressing of the wound, the blood continued to flow freely through the dressing and on to the bed. The patient complained of the præcordial pain, the cardiac dullness had distinctly increased, and the heart beats were faster and fainter than they day before. A continuance of the treatment was prescribed, also cupping on the præcordial region was ordered. The dressing of the wound was changed as often as it was necessary. The temperature in the evening was 101°3° F.

During the night the patient, who complained greatly of pain in the abdomen, diverted the attention of the nurse for a moment, got up from the bed, seated herself on an inverted vessel, and, leaning against the wall, gave birth to a child, who appeared vigorous and perfect. The nurse became aware of what was happening, and found, to her great surprise, the fætus connected with the placenta by an umbilical cord which was flabby and discolored. The mother complained of severe abdominal pains, but the præcordial pain was less intense, and the beating of the heart was fast and faint, although not irregular. Absolute rest was prescribed.

On the 13th the temperature was 97.7° F., the abdominal pain was very distressing, and the patient manifested great dread at the thought of having any one touch her abdomen. Meanwhile the nurse found that the flow of blood from the vagina was normal. On auscultation of the heart, it still remained the same, and the dressing of the wound continued to be saturated with a quantity of sero-sanguinolent liquid. The temperature in the evening was 99.4° F.

On the 14th the temperature was 98.2° F. The patient asked for food, she seemed to feel better, and she looked more rested, although the pracordial pain was still acute. The liquid which flowed from the wound seemed to diminish, and it was less sanguinary; there was no appreciable modification of the sounds of the heart, the dullness was still very extensive, and there was a slight odor about the wound, in spite of the careful

dressing of iodoform. In the evening the temperature was 100° F. There was great difficulty in breathing, and the patient had to be supported with pillows. At no time was difficulty of swallowing perceived or any abdominal symptom.

On the 15th the temperature was 1014° F., and the patient was weaker. The pulse, equal on both sides, was rapid and feeble; the præcordial dullness, already very considerable, was still more pronounced, the heart beats were fainter, the breathing was heavier, and it seemed for a moment as if air had entered the wound. There was a little diarrhæa. Another application of cups was prescribed, which did not, however, bring the desired result. In the evening the temperature was 102° F.

On the 16th the temperature was  $100^\circ$  F., the flow from the wound, which had been arrested, began again, and grave local and general symptoms persisted. The temperature in the evening was  $100^{\circ}$ ° F.

On the 17th the temperature was 102° f.; the general condition was aggravated, the cyanosis was more intense, there was a little subdelirium, the præcordial dullness was enormous, the sounds of the heart were more distant, and the bleeding had ceased. The patient died at midnight.

The autopsy showed a single injury of the sternum, about three millimetres in diameter, with well-defined borders. The wound was situated on the right side of the sternum, near the median line and above the sternal insertion of the fourth rib. Along the tract of the injury were pieces of splintered bone. The pericardium, distended and fluctuating, presented, at a point corresponding to the sternal injury, a black, sanguinolent opening, stopped up by a clot of blood and surrounded by a little emphysematous areolar tissue. This opening was single and very well defined. When the sternum and costal cartilages were raised, the excessive enlargement of the pericardial sac was to be seen reaching as high as the clavicle; on the left side in contact with the ribs as far as the axillary line; on the right almost passing beyond the right edge of the sternum; and from before backward extending from the sternum to the spinal colump, from which it was separated by the vessels and the œsophagus; below, the pericardium was not perceptibly extended, only to the level of the sixth rib.

On opening the pericardium, a lemon-colored liquid, in which were some light, fibrinous flocks, ran out. Light, frothy clots floated on this liquid, which had filled and distended the pericardial sac; a light, muddy liquid, in which were some more fibrinous flocks adherent to the serous pericardium. This liquid was removed, by taking it up in the hollow of the hand, into the space shut in by the distended pericardium. The heart had fallen to the bottom of the sac. The walls of the pericardium did not fall in, but kept the position caused by the distention, showing distinctly the form of a triangular pyramid at the base of the pericardial sac. The heart showed a small, round wound about three millimetres in diameter, situated about half-way between the apex and the auriculo-ventricular groove on the right border of the heart. This wound, which was single and not very deep, involved only the thickness of the wall. It ended in the network of the inner muscles of the heart, which had prevented the further penetration of the bullet. At the bottom of the pericardium two bullets and two small splinters of bone which had been carried with them were found. The bullets were enveloped in a very thin magma of fibrin. After the heart had been opened, in order to ascertain the non-existence of penetration, discolored spots corresponding to the exterior wound were seen at the posterior and external part of the principal muscle of the tricuspid. No other lesion of the heart was noted.

From a diagnostic point of view, the absence of hæmor-

rhage, the perfect preservation of the cardiac rhythm, and the absence of abnormal heart sounds would be sufficient cause to make lesion of the heart sounds, the praceordial pain, the bulging, and the heart sounds, the praceordial pain, the bulging, and the enormous effusion into the pericardium, with the abundant serous flow from the wound, proved that lesion of the serous pericardium did exist. The absence of symptoms in other organs (pleura, œsophagus, and lungs) compelled the admission that the lesion of the pericardium was isolated. As for the foreign substances found in the pericardium, which probably had been the principal cause of the pericardial irritation, their presence could only have been suspected, no symp-

tom of it having been observed. With regard to the treatment, in Dr. Morer's opinion, it had been altogether insufficient. At the end of the fourth day occlusion had been attempted, in the endeavor to diminish and finally to stop the flow, which was the safety-valve of the pericardium. Fortunately, it had not been successful, as was shown by the saturated state of the dressing, which had had to be changed several times during the day. Is this treatment with occlusion, the author asks, always justified? In his opinion, never. It is a convenient way, in the beginning, of concealing the surgeon's inability, but it is absolutely injurious to the wounded person, as was proved in 1877 and 1878 in the researches of F. Franck and his pupil Lagrolet. According to them, sanguineous effusion, as soon as it has become of a certain importance, compresses the auricles, and consequently the flow of blood toward the heart is suppressed, and then the ventricle, and finally the heart, ceases to beat. If the blood is effused outside of the pericardium, there is no danger except from the abundance of the hamorrhage.

If the external flow of blood is not very abundant, one must remain a spectator, so to speak, of the event, contenting one's self with dressing the wound antiseptically. But if the wound is large and gaping, and blood flows from it at each contraction of the heart, then one must confine himself to moderating the beatings of the heart, which, concealed by an antiseptic dressing, increase the hemorrhage which it is impossible to stop using applications of ice to the præcordial region, with bloodletting, as recommended by Rose, with absolute rest, and with injections of morphine. The first danger having been overcome, it is best to relieve the heart with repeated tapping rather than to reopen the wound, thus dealing only with the portion of blood that remains liquid, without disturbing the clots which may have formed.

There is thus some possibility of putting off rapid death and of awaiting the moment when, within the bounds of possibility, all fresh hæmorrhage will be averted. When this is achieved, if matters become more serious, owing to inflammation of the pericardium, or especially of the heart, revealed by the increase of temperature and the dullness, præcordial pain, circulatory troubles characterized by cyanosis, etc., there should be no hesitation in tapping the serous pericardium. This operation, if it had to be repeated, would without doubt be sufficient in case of serous effusion or sero-fibrinous effusion like that observed in the case mentioned. If at first, or during the course of treatment, the tapping reveals pus, a large opening should be made in the serous pericardium, a practice which is still to be followed if an abundance of clots is indicated. M. Morer prefers this method to making use of medicinal means, which are, unfortunately, he says, ot doubtful efficacy.

The following treatment is prescribed for the inflammation: Revulsives, bromides, ice to the præcordial region, etc., to quiet the movements of the heart. Digitalis, which increases the vascular tension and the impulsive force of the heart, is

contraindicated. Of course, the most rigorous asepsis is indispensable, and the author would not venture to affirm that the inflammation in this case had been influenced unfavorably by insufficient asepsis of the wound or by the puerperal condition of the wounded person.

An Artificial Medium for Tuberculosis Cultures.—E. A. de Schweinitz, Ph. D., of the Biochemic Laboratory, Department of Agriculture, Washington, writes to us as follows:

In March, 1893. I made a note \* of the use of Fermi's modified solution of mineral salts for the cultivation of the tuberculosis and other germs. As in this a small percentage of peptone was added to the liquid, while it is desirable to obtain a medium, if possible, perfectly free from albuminoid matter, I have since found the following solution adapted to the growth of the tuberculosis bacillus:

The multiplication of the tuberculosis bacillus upon this liquid is not quite so rapid as on one containing peptone, but is equally characteristic and is promising for further study. Its use may prove of service to other investigators.

The New York Academy of Medicine.—The special order for the meeting of Thursday evening, the 1st inst., was a paper on The Prevention of Disease, by Dr. W. W. Potter, of Buffalo.

At the next meeting of the Section in Public Health, Legal Medicine, and Medical and Vital Statistics, on Wednesday evening, the 7th inst., the chairman, Dr. J. West Roosevelt, will read a paper on The Protection of the Water-supply of Cities in this State.

At the next meeting of the Section in Surgery, on Monday evening, the 12th inst., Dr. W. T. Bull will read a paper entitled Further Observations on Chronic Relapsing Appendicitis.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 13th inst., Dr. R. W. Taylor will read a paper on Cancer of the Penis and the Groin.

At the next meeting of the Section in Neurology, on Friday evening, the 16th inst., Dr. Charles H. Knight will read a paper on Reflex Disturbances allied to Lesions of the Rhino-pharynx; Lightner Witmer, Ph. D., of Philadelphia, will read one on Pain from the Point of View of the Psychologists; and a gentleman whose name is not announced will read one on The Physiology of Deglutition in its Relation to the Nervous System.

The Medical Society of the District of Columbia.—The programme of the celebration of the seventy-fifth anniversary, to be held at the National Rifles' Armory Hall, G Street, between Ninth and Tenth Streets, N. W., Washington, D. C., on Friday, February 16, 1894, beginning at 7.45 p.m., includes the following titles of addresses: Address by the president, Samuel C. Busey, M. D., LL. D.; Address of Congratulation, by Theophilus Parvin, M. D., LL. D. (representative of the College of Physicians of Philadelphia); The History of the Medical Society of the District of Columbia, by W. W. Johnston, A. M., M. D.; The History of the Hospitals of the District of Columbia, by J. Ford Thompson, M. D.; and The History of the Medical Colleges of the District of Columbia, by Thomas O. Smith, M. D. A banquet will be given to the specially invited guests at the Arlington.

## THE NEW YORK MEDICAL JOURNAL, FEBRUARY 10, 1894.

Rectures und Addresses.

## LECTURES ON THE DIAGNOSIS OF ABDOMINAL TUMORS.

BY WILLIAM OSLER, M. D., PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

LECTURE I .- TUMORS OF THE STOMACH.

(Concluded from page 134.)

Case IX. Nodular Tumor Mass in the Region of the Pylorus; Dilatation of the Stomach.—Rachel C., aged sixty-two years, admitted February 13th, complaining of a lump in the right side of the abdomen. Mother died of pulmonary tuberculosis.

With the exception of pulmonary hæmorrhages, of which she has had in all nine attacks since her nineteenth year, and an attack of transient left-sided hemiplegia of five days' duration, she has been a healthy woman. Has had ten children. No special history of dyspepsia.

On September 15th she had for the first time severe pain in the upper part of the abdomen, which continued for nine days, and was intense enough to keep her from sleep. Soon after this she felt a lump in the right side, which has all along been painful and associated with a dragging feeling when she lies on the left side. At intervals she has a puffed, distended feeling in the abdomen with diffuse soreness. Her appetite has been poor, and she has had nausea sometimes after eating, and has several times at night had attacks of vomiting. She has had no swelling of the legs. The urine is clear; no special diminution in amount. Patient is emaciated, sallow; tongue coated, white; pulse is 88, regular, tension a little increased. There is a soft systolic murmur at the apex; with the exception of hyperresonance in the front and sides, and exaggeration and prolongation of the expiratory murmur, there are no changes to be noted in the lungs.

Abdomen.-There is a slight prominence in the right hypochondrium, and on inspiration a tumor mass can be seen to deseend in the parasternal line. On palpation in this region, just below the costal margin, there is a hard, rounded mass, the outline of which can be pretty clearly made out toward the median line, but toward the right it is apparently continuous with the margin of the liver. It is superficial, nodular, hard, and very painful. On deep inspiration, it descends almost to the level of the navel, and the fingers can be then placed between the tumor and the liver margin, and it can be held down. Gas can be felt bubbling through the mass. On percussion, there is a flat tympany. When quiet and in repose no peristalsis can be seen as a rule. When the patient turns over on the left side the mass falls forward and to the left, and can readily be grasped between the hands. The epigastric region is a little flattened; sometimes distinctly depressed. The lower umbilical region, on the contrary, is full.

On dilatation with tartaric acid and bicarbonate of sodium, the stomach is seen to be depressed and dilated. The lesser curvature passed just at the level of the navel; the greater curvature at a distance of seven centimetres below. Waves of peristalsis were then seen in the stomach walls passing from left to right, and sometimes the organ showed an hour-glass contraction.

The test breakfast showed the presence of the organic acids, absence of free hydrochloric. Material washed out was dark in color and smelled very sour.

The liver is not enlarged; the spleen not palpable; no enlargement of the external glands.

Case X. Enormous Dilutation of the Stomach, forming a Visible Tumor; Ridge-like Thickening in the Pyloric Region .-Emma H., aged thirty years, colored, admitted (to the gynæcological ward and transferred) April 28, 1893, complaining of swelling of the abdomen, nausea, and vomiting. Nothing of any moment in the family history. She was healthy until about eight months ago, when she began to have dyspepsia and distress after eating. She has not infrequently had attacks of vomiting. Lately she has been much nauseated after eating, and has had pain and swelling of the abdomen, with much belching. Six months ago she brought up food mixed with blood. Lately she has only been vomiting food. She has lost in weight within the past year, and has noticed that she passes much less urine than formerly. The patient is moderately wasted; weight, a hundred and five pounds; lips and mucous membranes of good color. Temperature normal; pulse, 112. The abdomen is flaccid, but a little prominent, and, on inspection, very marked waves of peristalsis are seen passing from left to right. They occupy a considerable area, extending from just below the costal margin to midway between the pavel and the pubes. As they pass, the skin is lifted in very definite prominences. On palpation, there is very marked succussion, and, on changing from side to side, the dullness alters as the fluid sags with the change of position. On inflating the stomach, it is found to occupy nearly the whole abdomen. The tympany begins above at the fifth rib and extends to the pubes.

The lesser curvature is seen just above the umbilicus. There is very prominent distention in the pyloric region, and the gastric tympany extends nearly to the right anterior superior spine. No nodular masses or tumor could be felt. With the stomach tube a large quantity of a greenish-vellow liquid with remnants of food was removed. When the stomach was emptied there then could be felt midway between the umbilious and the costal margin a ridge-like mass about the size of the thumb, which was freely movable and descended with inspiration, and which subsequent examinations showed was extremely variable, not being palpable when the or-

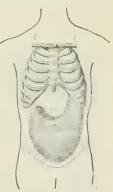

Fig. 8.—Outline of the stomach in Case X, showing the position of the tidge-like mass,

gan was very greatly distended. With lavage and feeding at short intervals the patient improved very much and the stomach reduced very materially in size and she gained in weight.

From the prolonged history of dyspepsia and the fact that she had on several occasions vomited blood, this was very probably an instance of dilatation from the cicatrization of an ulcer; and the small, elongated nodular thickening in the region of the pylorus also suggested this condition.

General Remarks on the Diagnosis of the Tumor caused by Dilated Stomach.—Inspection gives most important information, the value of which may be gathered from the fact that in these ten cases the diagnosis was made de visu. Bear in mind, in the first place, that a dilated stomach may occupy every region of the abdomen except the upper part of the epigastric and may form a very prominent tumor. The photographs (Figs. 9 and 10) which I show you illus-

trate this very well. They were taken during life from a woman, aged sixty-five years, who was admitted to the hospital complaining of attacks of vomiting which had per-

sisted for nearly two years, during which time she had become gradually emaciated and very weak. She had at intervals brought up enormous quantities of fluid. On inspection, the abdomen was greatly distended, particularly on the left side and in the umbilical and hypochondriac regions. It was uniform, but at intervals there were slight irregularities and elevations; no marked waves of contrac-

tion. On palpation, the abdomen was everywhere soft, except at a point to the right of and just below the navel, where there was a hard, resistant mass. At first it seemed scarcely possible that the entire abdominal distention could be due to a dilated stomach, but the reduction in size after vomiting and after lavage, the depth to which the stomach tube could pass, and the irregular waves of protrusion left no doubt that the distention was due to an enormously dilated stomach. She died November 16, 1889. The photo-

graphs (Figs. 9 and 10) show the profile and front views taken during life, and Fig. 11, from a photograph taken after death, shows the position of the organ and its enormous enlargement. There was cancerous stricture of the pylorus.

The most prominent distention is usually in the left half of the umbilical region, but it may be chiefly below the navel.

Fig. 11.—Showing the position and size of the stomach in Sarah A. From a photograph taken at the autopsy.

A definite stomach contour may be seen very plainly in many instances of dilatation from stenosis of the pylorus. At intervals, during the contraction of the stomach walls, the outline of the greater curvature descends on the left side, curving at a level of the anterior superior spine, and passing to the right at a variable distance above the pubes, sometimes not more than three or four centimetres, sometimes midway between the pubes and the navel. Curving upward, it ends either in the left lumbar or more frequently in the right upper quadrant of the umbilical region, sometimes appearing to pass beneath the right costal margin. The lesser curve is frequently much more distinct, the line passing vertically parallel with the left border of the sternum or in the parasternal line, curving to the left of the navel, and often during the contraction of the organ forming a very well marked, sharply defined contour at or a little below the level of the navel. I have found the greatest surprise expressed by practitioners that the stomach should be so low, that even the lesser curvature should be below the level of the navel; but this is frequently the case in extreme dilatation. In the first place, then, the outline of the organ may give to you at a glance the diagnosis. Secondly, inspection is of the greatest value in determining the presence of peristalsis. Though enormously stretched, there is hypertrophy of the muscular coats and great increase in the activity and frequency of the movements. In all of the cases they were present. The movements are of two kinds, which may be seen together or separately: First, peristaltic waves, passing slowly from left to right, more rarely antiperistalsis, from right to left. The mere exposure of the abdomen to the cool air is usually sufficient to excite them. Sometimes the stimulus of palpation is required, or the flapping of the skin with a wet towel. During the passage of these waves the outline of the organ becomes evident; sometimes, as already noted, the greater and lesser curvatures are plainly to be seen. Sometimes, too, as the waves reach the pyloric region a tumor mass may be rendered visible or made more prominent. The stomach may be so enormously dilated that the walls are in a condition of paralytic distention and no peristaltic waves are seen, as in the case from which Figs. 9 to 11 were taken.

A second variety of movement to be seen in a dilated stomach consists in a slowly performed irregular protrusion here and there of the stomach wall, which lifts the skin of the abdomen in a hemispherical boss or prominence. This may develop at any point, more frequently toward the greater curvature. They usually occur with the peristaltic waves and in combination may throw out in bold relief the contour of the organ, sometimes also giving to it a somewhat hour glass shape, owing to corresponding depressions about the middle of the greater and of the lesser curvatures. The upper depression is seen in Fig. 1. These irregular protrusions may be seen in enormously dilated stomachs, in which the peristaltic waves are no longer visible, as in the case just mentioned, of which I have shown you the photographs. Let me again emphasize the value of inspection by reminding you that of the thirteen instances, in ten the diagnosis was manifest on inspection

Palpation.—Four points may be determined by this procedure. The existence of the splashing sound or succussion, the clapotage, which is always present, and which, though in no way diagnostic, yet is of value in connection with a prominence in the left flank and lower umbilical region. It is of use also in determining the lowest level of the organ. With the hand on the abdomen, as the peristaltic waves pass, or as the irregular protrusions develop, you will notice that the organ hardens; and toward the pylorus, as the wave is followed, there may be an exceedingly firm contraction. After persisting for a minute or so the muscular walls relax and are again soft and readily depressed. In some instances the muscular contraction at the pylorus is extremely firm and hard, and the relaxation beneath the hand reminds one of that of the uterus. A third point of importance, particularly in palpation of the pyloric region, is the gurgling of gas through the pyloric orifice. This is usually very marked when the stomach is inflated, but it may occur spontaneously and in some instances at regular intervals. In doubtful tumors of this region this is a sign to which scarcely sufficient attention has been paid. Its importance will be referred to again in

connection with tumors of the intestines, as in one case in the series it saved us from a somewhat serious error. And lastly it is by palpation chiefly that we are enabled to determine the presence or absence of a pyloric tumor. And here you have to bear in mind that in dilatation of the stomach the pyloric tumor may be extremely variable. readily felt to-day, scarcely palpable to-morrow, dependent very much upon the grade of distention. You will find this very strikingly illustrated after washing out the stomach, when perhaps a comparatively small pyloric mass may be found to be quite large and prominent. When the organ is extremely dilated, the tumor may be scarcely palpable. This was particularly well illustrated in Case VII. which was sent to me by Dr. Salzer for an opinion as to the advisability of a Loretta's operation. The tumor at the pylorus, which at the first examination seemed not larger than a walnut, after thoroughly emptying the stomach was found to be a solid mass the size of an egg.

Percussion combined with palpation brings out most clearly the splashing sound, which in cases of extreme dilatation may be most evident below the transverse navel line. The extent of stomach tympany will vary with the position of the patient. In the recumbent posture it may extend in the nipple line from the fifth costal cartilage to within two or three fingers' breadth of the pubes. In the erect posture a line of transverse dullness may be accurately defined, which will sink as the patient is gradually placed in the recumbent position. The extent of stomach tympany varies, of course, with the amount of fluid contents, and after the attacks of vomiting in which large quantities of liquid are brought up it may be very much extended.

In doubtful cases inflation of the organ is a most valuable method, and is best accomplished by the use of the bicarbonate of sodium and tartaric acid, from half a teaspoonful to a teaspoonful dissolved separately and taken one after the other, the patient being directed to refrain, as far as possible, from belching. Inspection may, through thin abdominal walls, at once reveal the distended stomach, displaying active peristaltic movements. The percussion limits can then be also more definitely defined. Palpation in the pyloric region may give the sensation of gas bubbling through into the duodenum. This method of inflation is more satisfactory on the whole than that of pumping air into the stomach. When gastric ulcer is suspected these proceedings should be practiced with great caution or omitted altogether.

Auscultation gives little information of value. One hears the sizzling sound of the gas as the contents of the stomach are churned about; sometimes quite loud gurgling is heard as the fluid passes through the pylorus, often loud enough to be heard at a distance. The succussion splash may be obtained by placing the ear upon the abdomen, and either shaking the patient or asking him to depress suddenly the diaphragm.

The characters of the contents of the dilated stomach, the general symptoms, and special features I shall not discuss, as the subject before us is more particularly the form of abdominal tumor caused by it. To one special point, however, I may refer, as it is of some moment in the treat-

ment of these cases of dilatation from stenosis of the pylorus. The recent experiments of von Mering show that water is not absorbed to any extent from the stomach, but is passed into the intestine, usually at regular intervals, by a rhythmical opening and closing of the pylorus. Not only is the resorption of water extremely slight, but hand in hand with the absorption of the sugars and peptones there is actually a secretion of water corresponding in some measure to the amount of substances absorbed. these facts correspond closely certain points in the history of dilatation of the stomach. The organ is never empty, and even after it is pumped out as much as possible, fluid will reaccumulate without any liquid having been taken; and frequently patients will remark in astonishment that the amount which they have vomited far exceeds in quantity what has been taken by the mouth. This explains also other striking symptoms in excessive dilatation of the stomach-namely, the great reduction in the amount of urine secreted, the dryness of the skin, and the wasting, which is proportionate to the degree and persistency of the dilatation rather than to the nature of the obstruction. Unverricht has suggested to supplement this water depletion by the use of large enemata, two litres daily of salt solution, the use of which he states has been followed by marked improvement in the symptoms, and in some instances by an increase in weight.

And, lastly, there is the question, What conditions may be confounded with dilatation of the stomach? Nothing, in reality, if the examination is made systematically and thoroughly. The physical signs alone are generally sufficient, and, when taken in connection with the general symptoms, quite distinctive; thus there was not one of the cases in this series about which a shade of doubt existed. Yet mistakes have arisen, some of a remarkable nature, owing to ignorance of the fact that the dilated organ may be chiefly to the left of and below the umbilicus. The tumor has been mistaken for an ovarian cyst (Detroit Lancet, January, 1880), and even after tapping and the withdrawal of a dark-colored fluid containing grains of rice, pieces of potato, bread, meat, etc., laparotomy was performed for ovarian tumor. The enormous dilatation, as shown in Figs. 9 and 10, with paralytic distention and absence of the peristaltic waves, might, and indeed did, when the stomach was very full, simulate ascites, but no serious difficulty could arise in the differentiation. Tumors of the colon, causing obstruction, lead to great distention of the large bowel, in which active waves of peristalsis may be seen passing from right to left. Usually the abdomen is distended more uniformly or chiefly in the epigastric zone, and intestinal, not gastric, symptoms have been present, and the inflation of the stomach alone, or, if practicable, combined inflation of the stomach and colon, will usually give information upon which you may base a definite conclusion.

A dilated stomach, causing a prominent tumor of the abdomen, is almost invariably due to stenosis of the pylorus. As already mentioned, in all of the cases a tumor was evident, and in all the condition was that to which the term dilatation of the stomach is more correctly limited. In rare instances a prominent tumor may be caused by muscular

insufficiency, as it is called, or atony of the stomach, and occasionally, by change in the position of the organ, the socalled descensus ventriculi. The differential diagnosis of these conditions you will find fully given in the special works above mentioned. I may, however, remark that only in very exceptional instances of atony of the stomach or of descensus ventriculi are the peristaltic waves seen. In women who have borne many children, and who have the extremely relaxed abdominal walls, the condition which Glénard has termed enteroptosis may be associated with great depression and enlargement of the stomach. In some cases the decision is very difficult. I show you here the stom ach outlines of a patient who at first we thought had dilatation of the stomach from pyloric obstruction. The organ reached nearly to the pubes; the lower curvature was, however, at the umbilicus. The vertical measurements of the stomach were twenty centimetres in the middle line, thirty-one centimetres from the lower border of the eighth costal cartilage to the middle of Poupart's ligament, and the transverse diameter twenty-eight centimetres and a half. Occasionally there were to be seen peristaltic waves crossing from left to right. No tumor was at any time to be felt. The liver was depressed; the kidneys were movable. The examination for free hydrochloric acid was variable; sometimes it was present, sometimes absent. She had had dyspepsia for some years, and within the year much belching and some vomiting, but never of very large quantities of liquid. With lavage and careful dieting she improved very much, and gained fourteen pounds in three months. We subsequently lost sight of her.

II. Tumor formed by Contracted Stomach.—There are two conditions in which the stomach itself, in a state of contraction, may form a definite, palpable tumor—first, in occlusion of the œsophagus, when the organ shrinks and may be sometimes felt as a narrow, firm cord, lying below the margin of the left lobe of the liver; and, second, when there is diffuse thickening of the stomach walls with contraction of the lumen in cirrhosis or in diffuse cancerous infiltration. The following is a remarkable instance of the latter condition, which presented a well-marked tumor:

Case XI. Tumor in the Epigustric Region, consisting of the Stomach diffusely Infiltrated with Carcinoma.—George H., aged sixty years, tailor by occupation, German, admitted on April 4, 1893, complaining of indigestion.

Has always been strong and well; had gonorrhee when twenty; has been a moderate drinker; does not use tobacco.

Present illness began about five months ago with uncomfortable feelings in the epigastrium and constipation. Prior to this he states that he had no dyspepsia. Soon he began to have much distention after meals, and water brash. He has never had any vomiting, but he spits up a great deal of mucus. There is sometimes a sharp pain in the abdomen, but, as a rule, there is only a heavy, uneasy sensation after eating. In January he noticed that there was a swelling above the left clavicle. In March he had one or two attacks of vomiting, and he has been much troubled with hiccough.

He applied at the dispensary about the end of January, and a stomach tube was introduced, but it brought up a little blood. Since his illness began he has lost forty-five rounds in weight.

Present Condition .- Considerable emaciation; lips and mu-

cous membranes of good color. Above the left clavicle the lymph glands are enlarged and bard; slightly enlarged above the right. They are also somewhat enlarged in the inguinal region. The thoracic organs are normal.

The abdomen is flaccid, symmetrical; a little full, perhaps, in the epigastric region. On palpation, a ridge-like mass is to be felt in the left hypochondrium, which extends across the middle line to the right side as far as the parasternal line. It descends with deep inspiration as low as the umbilicus. The

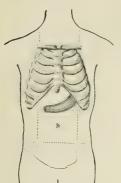

Fig. 12.-Showing the position of the tumor mass consisting of difusely infiltrated stomach walls in Case XI.

law as the water than the law and feels somewhat like a rolled omentum. It can scarcely be separated above from the liver, the edge of which is just palpable. There is a flat tympany over the mass. On inflation of the stomach, vomiting occurred and a good deal of distress.

The urine was negative.

On April 21st the patient had tenderness along the saphenous vein and the calf of the leg, and there was edema of the ankle and of the leg.

The patient left hospital on May 5th, and died two days afterward at his home, where the autopsy was made by Dr. F. R. Smith and Dr. F. Fincke, who brought the specimens to the laboratory. There was nothing of special note in the tho-

racic organs except that there was some adhesion of the layers of the pericardium.

The peritonæum was smooth. The stomach, intestines, and mesentery were removed together. The liver was not enlarged, was a little granular on section, and firm. The omentum was uninvolved. The stomach was free on its anterior wall, on the greater part of the posterior wall, and on the greater curvature, but was closely adherent at the pyloric zone to the contiguous parts. The organ was reduced in size, measuring in its extreme length thirteen centimetres; transverse diameter, from four to five centimetres. It was extremely firm and dense, and the tumor mass which was felt during life corresponded to it, and the hard, resistant edge corresponded to the greater curvature. The orifices were not narrowed; the walls were extremely thickened, from eight to ten millimetres at the cardia, and from thirteen to fourteen at the pylorus. The thickening was due partly to the great hypertrophy of the muscularis, but chiefly to the submucosa, which measured from three to five millimetres. The mucous membrane was uniformly smooth, excessively thin, and showed no erosions or ulcerations.

On micro-copical examination, the mucous membrane was almost entirely deficient. The submucosa was occupied by large groups of cancer cells between strands of connective tissue. The layers of the muscular coat were much hypertrophied, and, invading the interstitial tissue and sometimes in the muscular bundles themselves, were numerous cancerous cells

The pancreas was firm and hard and uniformly surrounded by thickened peritoneal tissue, intiltrated in places with cancerous new growth. The substance of the gland itself was normal. The mesentery was enormously thickened, neasuring close to the root three centimetres. The peritoneum was thickened, presenting in places flat areas of carcinoma, and the mesenteric glands were uniformly enlarged and cancerous.

While we regarded this case as one of cancer of the stomach, we certainly were not aware of its remarkable character. The tumor so readily felt was thought to be an infiltration of part of the stomach wall, whereas in reality it corresponded definitely to the organ itself. The diffuse infiltrating carcinoma has to be carefully distinguished from the true cirrhosis of the stomach, consisting of fibrous overgrowth. The distinction can, however, only be made by the microscope, unless, of course, there is secondary infection of glands and neighboring organs. In this instance the lymph glands were infected, and I would call your attention particularly to the fact that the supraclavicular glands on the left side were also involved-a situation in which secondary tumors are sometimes seen in cancer of the stomach and of the œsophagus, and in which their presence may be of the greatest value in diagnosis. Not only may there be a primary infiltrating carcinoma of the stomach not distinguishable macroscopically from cirrhosis of the organ, but Dr. Welch, in showing this specimen at the Hospital Medical Society, called attention to an instance which he had reported of secondary infiltrating carcinoma of the stomach in a woman, aged forty years, who had double carcinoma of the ovaries. This beautiful plate, in Carswell's Morbid Anatomy, illustrates the condition very

### Original Communications.

### OCCURRENCE OF INTERNAL ANEURYSM IN EUROPEAN RESIDENTS OF JAPAN.\*

BY STUART ELDRIDGE, M. D., TOROHAMA, JAPAN.

A REMARKABLE fact in the medical history of European residents in the Japanese ports—and the same is true within limits of certain of the Chinese cities open to foreigners—is found in the excessive proportion which thoracic and abdominal aneurysm bears to other causes of death. I can speak from personal observation only of the so-called foreign settlement of Yokohama in central Japan. This is the largest community of European blood existing in the Empire, and has probably averaged from two thousand to twenty-five hundred souls during the past twenty-two years, this being the limit of my experience. Of this population, adult males have always formed more than half, and are still in excess. As it is to this class that aneurysm is strictly confined, the bearing of this fact must be considered in dealing with the mortality lists.

And here let me digress to say that, coming as I have to the home country in search of rest and health, I am without my notes or case-books, and can by no means present the subject I bring before you as I could wish to do. Aneurysm in its severer forms has, however, assumed such overweening importance in my professional life that, without attempting to deal with exact statistics, I trust I

<sup>\*</sup> Read before the Society of the Alumni of Bellevue Hospital, December 6, 1893.

may be able to convey to you a fair idea of the relative prevalence, usual history, and characteristics of this disease as it is met with in foreign residents in the far East. During one term of seven years-1871 to 1877-for which I was able to obtain approximately accurate statistics, there were more deaths in the foreign community from aneurysm than were caused by any other disease with the exception of small pox and phthisis. I believe, however, that as an exceptionally severe epidemic of variola occurred in 1871, and one of less importance in 1875, being almost the last of their kind among us, vaccination of the native population as well as foreigners of course becoming general and most effective immediately subsequent to these outbreaks, while the greater number of deaths from phthisis were those of recent arrivals or strangers, aneurysm during this period was, in reality, responsible for a greater number of deaths of residents than any other one disease. The cases upon which I base this statement were almost without exception clearly diagnosticated before death, either by my able friend and colleague, Dr. E. Wheeler, or by myself, or by both in conjunction, and verified by autopsy, or, as often happens, first became known at the post-mortem table. To these, beyond a doubt, though this would but enlarge the proportion borne by aneurysm to other diseases, should be added a considerable number of instances in which the victims of sudden death were buried under certificate giving the indefinite diagnosis of "heart disease" or "hæmorrhage." This applies not only from 1871 to 1877, but throughout the term of my experience. That I am correct in entertaining more than a suspicion that such has been, and is still, the fact will, I think, be granted when I tell you that some knowledge of individual cases in which this error has presumably occurred, supplemented by personal investigation as to symptoms and mode of death, has all but absolutely demonstrated the mistake committed; that lesions of the heart itself are decidedly rare in the European community, perhaps from the equal infrequence of articular rheumatism; and that cerebral affections, killing suddenly, are, save from alcoholism of an extreme degree, almost as uncommon.

The term of seven years of which I speak was probably approximately that during which the proportion of death by aneurysm to the total mortality was greatest. While I can not speak with even equal statistical accuracy of the occurrence of the disease in question during the following term of seven years-1878 to 1884-I am sure I am within bounds in saying that its frequency, while somewhat less than during the just previous septennate, was still very excessive, and probably far beyond that known in almost any other body of men of equal numbers. Since 1884 I think it beyond dispute that we have met with a decidedly smaller proportion of cases of this disease, though it is still abnormally frequent as compared with other serious maladies. The presumed cause of this early excess and later decrease in the occurrence of aneurysm will be touched on later, when dealing with the presumably general or local factors of causation. During the nineteen years of my private practice in Yokohama I have personally had to do with some forty cases of fatal aneurysm, thoracic or ab-

dominal, within the resident European community. Nearly all of these were unmistakably recognized during the life of the patient, the diagnosis being confirmed post mortem. A few only were first detected in the deadhouse.

The experience of my friend and colleague, Dr. Edwin Wheeler, already mentioned, and also a practitioner of Yokohama for the past twenty years, has been singularly parallel to my own. While by far the larger proportion of cases have been within the individual or associated observation of the gentleman just named and myself, there have been others in the practice of almost every physician who has had professional dealings with the European residents.

I think I am not beyond the truth in asserting that, to the best of my knowledge, in this comparatively small community of two thousand to twenty five hundred people, including the classes not affected—viz., women and children—the deaths by aneurysm have during twenty years approximated to an average of five per annum.

As to the general character of the disease, I will say briefly that it attacks by preference the upper portion of the thoracic aorta, next the lower portion of the same, and less often the abdominal division of this great vessel. The proximal portions of both the thoracic and abdominal branches of the aorta are sometimes, though but rarely, affected. I have personally met with one case of aneurysm of the innominate, one of the left carotid at its origin, and one each affecting the splenic and right renal arteries. I have seen no case attacking the pelvic vessels except as the result of traumatism.

The excessive rarity of peripheral aneurysm in subjects so prone to the graver forms of this malady is most remarkable, and to me, upon any hypothesis, inexplicable. I have myself met with but one instance of the development of the disease in an artery of the limbs, and have reason to believe that aneurysmal dilatation of the cerebral vessels, whether macroscopic or microscopic, is nearly or quite as infrequent.

Comparatively rapid progress and early rupture is, I am inclined to think, almost universal, though to this I have known marked exceptions. While erosion of the vertebræ to a greater or less extent occurs in almost every aortic case, I have yet to see in a European resident in Japan marked absorption of either the ribs or sternum. Rupture generally occurs so early that, though the existence of the disease is comparatively easily determined by one of any experience, its location and extent can not be so defined as to warrant any attempt at surgical interference.

Now, to what are we to ascribe the excessive and altogether unusual prevalence of this important vascular lesion? It affects, or rather has affected, men of almost every position in life, although, as we have comparatively few absolutely poor people of European extraction in our community, the great majority of its victims have been men of relatively good social position, who had for years been in the enjoyment of ease and comfort, and not exposed to physical strain or to traumatic injuries of their vessels due to occupation. Nearly all the cases of the disease have occurred in those of prolonged residence in the far East, newcomers being as yet very infrequently attacked. I be-

lieve the great exciting cause of the disease to be syphilis, both on account of its undoubted effects upon the arterial system and because of the existence of a history of old and often severe venereal intoxication in most of the aneurysmal cases of which I am speaking. It is true that in some instances the closest investigation has failed to reveal evidence of syphilitic infection, but even here the circumstances and general medical history of the earlier European and American residents of Japan and China must be considered. When Japan was opened to foreign settlement, within limits, in the earlier sixties, syphilis had run riot among the natives for centuries, treatment of the disease being seldom administered and generally utterly inefficient. The result, so far as the natives were concerned, was that syphilis, acquired or hereditary, was in the lower classes almost universal, at least as concerns the urban population, while those of higher position could claim no exemption. It is a fact that—as was the case in the Iberian peninsula at the time of the Napoleonic wars, when, although Wellington's army of comparatively pure-blooded Englishmen was almost decimated by a peculiarly severe form of lues, the natives themselves appeared to suffer but little from its effects-the Japanese, considering the general distribution of the virus, rarely exhibited the graver and later lesions of the disease. Perhaps, as was supposed to be the case in the instance just quoted, a relative tolerance was acquired by inheritance. As suggesting the wide prevalence of syphilis at the time with which we are now dealing, it may be stated that in the year 1868, when the system of medical inspection and control of prostitutes, still in operation, was inaugurated by the lamented Dr. Newton, of the British Navy, examination of the frail sisterhood of Yokohama showed over ninety per cent. to be syphilitic, including those dealing with the native population, as well as the few filling the usual functions of their class as regards the seafaring and other foreign visitors.

The European settling in the far East in the earlier days found a community almost exclusively masculine; but few families were among the residents, and the softening, restraining, and elevating influences of good women were conspicuously wanting. The natural result followed; irregular connection with the lower class of native women was formed, though it should be said, in justice to these, that when ordinary precautions were taken cases of infection by regularly kept native mistresses have always been exceptionally uncommon. But these playthings, perhaps the least exigent of their kind on earth, exercised but little restraint upon their keepers, who, ranging at will through the enticing fields and gardens of a Japanese Cythera, often returned laden with an efflorescence which sometimes proved perennial. Undoubtedly alcohol and high living must be considered as also playing a part in determining the tissue changes which lie at the base of aneurysmal disease. Free and luxurious living was, and is still, almost universal among Europeans in Asia, though in many cases supplemented, and to a degree counteracted, by active exercise and anything but sedentary habits. I have said that I believe the great existing cause of aneurysm, as I have known it, to have been syphilis, and this belief is find no evidence that in regions where malarial influences

supported by the fact already mentioned-viz., that there has certainly been a progression and considerable diminution in the frequency of occurrence of the disease within late years. This is exactly what would have taken place supposing syphilis to be an essential element. Within the past fifteen years a marked change has gradually taken place in the social aspects of European communities in the Eastern world. The old Hong system, with its autocratic partners and crowds of highly paid and allowanced clerks, both unmarried, is a thing of the past. Money, when made at all, is made slowly and with labor. People come to stay for long terms or for life, bringing their families with them. The proportion of women to men has enormously increased, and there are many young girls, the whole forming a society which combines some of the best elements of life in Europe and America. From this has resulted a most decided improvement in the morals, and consequently in the health, of the community.

Another consideration which must be given due weight in this connection lies in the fact that even the best available treatment of syphilis was in the far East twenty or more years ago, as in some other countries at that time, most perfunctory and ineffectual. On the other hand, the vast majority of cases now met with and receiving enlightened modern treatment, sufficiently prolonged, I not only believe but know to be practically permanently cured. Still, though syphilis be the prime factor in the ætiology of the disease under discussion, there must be another determining cause. Syphilis, high living, and alcoholism are each and every one met with but too frequently elsewhere, and yet, so far as I have been able to ascertain, are nowhere followed by any such proportion of arterial disease as within the environment which we are discussing.

With regard to this unknown factor I have certain suggestions to offer, but they must be considered as suggestions only. The subject is as yet so obscure and all attempted solutions so entirely lack demonstration, or are, at least in appearance, so flatly contradicted by known facts, that he would be a bold man who, in the present state of our knowledge, should present a complete and rounded scheme of the pathology of the disease with which we have to do to-night. Is this undetermined influence of climatic origin? There are undoubtedly many reasons for believing that in humid climates, accompanied, as is often the case, by a comparatively limited range of temperature, as in England, to which in meteorological conditions Japan bears a considerable resemblance, aneurysm is exceptionally common. Certain parts of India and the coasts of China and Turkey are other cases in point. Au contraire, we are told that in Australia and California, where, I believe, the climatic conditions are essentially different, the disease is also very prevalent. Malarial intoxication has been suggested to me by my friend Dr. Wheeler as combining with syphilis to produce disease of the great arteries, at least in Japan. I find it difficult to believe this to be the fact. Malarial disease, though by no means uncommon in Japan, is generally of mild form, and chronic paludism of the marked and severer type is almost unknown, while I

are most widespread and injurious vascular disease of the form under consideration is at all general.

In this connection, and in view of the well-recognized association between diseases of man and of those domestic animals with which he is in closest relations-e. g., hydatid disease in Iceland-certain facts relative to parasitic maladies in the far East, where such diseases are rife, are worthy of mention. There, many forms of filariæ are known to attack both men and animals. Among these may be briefly noted: 1. The Filaria sanguinis hominis of Manson, producing lymph scrotum, chyluria, and often, finally, true elephantiasis. 2. Filariæ infecting the heart and vessels of the dog. 3. Filariæ attacking and burrowing in the wall of the dog's æsophagus, and there causing small abscesses, which later, by weakening the wall of the contiguous aorta, produce aneurysms. This latter I long suspected might possibly be responsible for at least a part of the aortic lesions I have met with, and whenever able I have carefully examined the esophagus in autopsies of cases of aneurysm, as well as other diseases, in the hope of finding evidence of existing or antecedent filarial infection. So far the result has been negative, though it should be said that as post-mortem examinations are rarely to be obtained, save in cases of sudden death, discovery of filarial lesions in their acuter stage, if made at all, would in all probability be accidental.

As to the treatment of internal aneurysm I have little to say. Iodide of potassium certainly exercises an almost magical effect upon the disease in producing relief of symptoms and, I feel sure, prolonging life to some extent. Tufnell's system, in one of several cases in which I have tried it faithfully, produced a somewhat encouraging though not entirely curative result. Surgical treatment I have already stated to be rarely practicable for the reasons given.

In conclusion, as I have had much to say in reference to syphilis as occurring in Europeans resident in the far East, a few additional remarks on this subject may not be without interest, although not directly connected with the subject of this paper. I do not think that syphilis, as contracted by Europeans in Japan and China, in any essential particular differs from that acquired by men of similar position and circumstances in Europe or America. I have already said that, under proper treatment-by which I mean mild prolonged mercurialization, all other treatment being accessory and symptomatic-the disease has been, in my experience, practically cured in the vast majority of cases. Witness families of children in robust health, the father in equally enviable condition, though having a history of perhaps severe and for a time neglected syphilis before marriage. Do not suspect from this that I allow my venereal patients to marry hastily, or without probation.

I meet among those personally treated from the beginning but very few lesions beyond the diagnostic roseola, nor do my patients often experience relapses, save when due to alcoholism or their own neglect. Even in apparently serious and inveterate cases—generally, I think, to be ascribed to insufficient or mistaken treatment in the earlier stage of the intoxication—syphilis in its deeper and more severe manifestations has been most rare within my observed.

servation. More especially is this true as regards syphilis of the nervous system, with the exception of a few isolated cases clearly due to gummata. Paresis of any origin, syphilitic or non-syphilitic, is conspicuous by its rarity, while that much-discussed disease or symptom, locomotor ataxia, is practically unknown.

Finally, let me beg you to remember that throughout I have been dealing with questions exclusively concerning people of European derivation, all remarks with regard to the native inhabitants being but incidental and explanatory. As, however, I have mentioned the former very general prevalence of syphilitic disease among the native population, it is but just to state that a very marked improvement has within late years occurred in this respect. When I went to Japan as a medical teacher the number of native physicians having any knowledge whatever of Western medicine might have been counted upon the fingers; today there are between five and six thousand native physicians practicing, to the best of their ability and opportunities, scientific medicine and surgery. Among these there is no inconsiderable number of men thoroughly educated, either abroad or at the University of Tokio, and some the equal of any men of their age and experience elsewhere. To this, more than to the system of governmental inspection and control of prostitution, I ascribe the very decided abatement of syphilitic disease. As a word of warning to intending visitors to Japan-this for transmission to your friends or patients, men of our profession never exposing themselves-let me conclude by saying that, for reasons unnecessary to enter upon now, governmental control of the brothels is, in a prophylactic sense, no more, perhaps less, effective than in other regions where it has been tried. Clandestine prostitution, at least in the open ports, has increased pari passu with the stringency of discipline in the regular army of Venus, and there are few parts of the world more dangerous to the unsophisticated globe trotter than fascinating, childlike, beautiful, glorious Dai Nippon.

## TWO CASES OF RAPIDLY PROGRESSIVE GANGRENE

IN WHICH PURE CULTURES OF THE BACILLUS PYOCYANEUS WERE FOUND.
BY GEORGE RYERSON FOWLER, M, D.,

BROOKLYN, SURGEON TO ST. MARY'S HOSPITAL AND THE METHODIST EPISCOPAL HOSPITAL.

Case I.—J. B., aged thirty-one years, fishmonger. On November 18, 1892, I was requested by Dr. Curran to visit this patient in consultation. The following history was obtained: Two days previously, while cleaning fish, he received a wound from a fin upon the palmar surface of the distal phalaux of the left middle finger. The wound was a trifling one and attracted but slight attention at the time. Within a few hours, however, the finger became extremely painful and greatly swollen. The entire finger assumed a purplish-blue appearance, and several blebs filled with dark serum appeared upon the dorsal surface. When seen by me the local infection extended to the metacarpal region, and the finger itself was in a condition of gangrene from an overwhelmingly rapid infiltration of all its soft structures.

The patient's condition indicated a more than usually severe general infection. The pulse was 130 and the temperature 108° F. The countenance was anxious, the skin bathed in a moist, profuse perspiration, and in his general demeanor there were the evidences of a profound disturbance of the nervous system, as shown by a general uneasiness, anxiety of countenance, and sleeplessness. The usual accompanying symptoms of the febrile state—namely, anorexia and furred tongue—were present.

Immediate operative interference, for the purpose of getting rid of the local source of infection, was advised and accepted, and he was removed to St. Mary's Hospital for that purpose. On the afternoon of the same day I amputated the finger, and removed at the same time the greater portion of the corresponding metacarpal bone and dissected freely away the gangrenous tissues upon the back of the hand.

Within a few hours the patient's temperature fell to normal, the pulse rate lessened, and a general improvement followed. The wound, which had been dressed with moist compresses of Laplace's solution (mercuric chloride, 1 to 1,000; tartaric acid, 5 to 1,000), became and remained aseptic and rapidly healed by granulation.

Stab cultures of sterilized gelatin culture tubes were made of the contents of the blebs, and from the tissues of the finger, from which Dr. Bristow obtained, at the Hoagland Laboratory, pure cultures of the Bacillus pyocyaneus (Gessard).

CASE II .- I. N., aged thirty-five years, was admitted to St. Mary's Hospital on January 5, 1892, suffering from an exceptionally severe attack of appendicitis. He had been attacked upon the preceding day with symptoms which indicated a more than usually severe and rapid form of the disease, as shown by the intensity of the local tenderness, as well as by the profound prostration and other grave constitutional symptoms. The abdomen was at once opened by a right lateral laparotomy. The appendix was found to be gangrenous from the tip to within a quarter of an inch of its base. It lay buried in a layer of plastic lymph, which, fortunately, had shut it off from the general cavity of the peritonæum. This layer of plastic lymph was of the same greenish black color as the appendix itself. Considerable difficulty was experienced in isolating and removing the appendix without disturbing the slightly adherent and thin layer of isolating new-formation tissue. In this, however, I was finally successful. The cavity from which the organ was removed was carefully tamponed with sterilized zinc-oxide gauze, and the abdominal wound dressed with compresses of the same. All went well with the patient at first. The temperature and pulse-rate showed a decided tendency toward the normal from the first hour. The wound, as is my custom, was not disturbed for the first forty-eight hours. At the end of this time it was discovered that the patient's condition had changed for the worse. The temperature became elevated and the pulse quickened; some uneasiness on the part of the patient was also present. Upon removing the dressings, it was discovered that a gangrenous condition of the abdominal walls existed, extending from the inner margin of the wound toward the median line, occupying an area of about four inches. Numerous blebs were present, filled with dark-brown serum. The gangrenous portion was removed down to the muscular structure, which up to this time had escaped.

The parts were thoroughly cleansed by means of the acidsublimate solution, and both the cavity from which the appendix was removed as well as the infected abdominal wall were dressed with moist dressings of the same. These were frequently changed. The wound soon assumed a healthy appearance, the pulse and temperature fell rapidly to the normal, and the patient eventually made a complete and satisfactory recovery. Stab inoculations in culture tubes of sterilized gelatin, derived both from the contents of the blebs and from the gangrenous tissue, were made and investigated, with the result of showing the presence of the Bacillus pyocyaneus. No other micro-organism was found.

The special interest to be attached to these cases depends upon the bacteriological findings, taken in connection with the clinical conditions present. In both the same phenomena of sudden and rapid supervention of grave constitutional symptoms, in conjunction with a rapidly progressive gangrenous local condition, marked the course of the case. In both the same rapid improvement followed removal of the gangrenous area and vigorous antibacterial local treatment. Finally, in both the same micro-organism, and that of the class to which but slight pathogenetic importance is usually attached, was found in pure culture.

The question of the pathogenetic importance of this bacillus is of considerable interest at the present time. Former observers have considered its presence of but slight moment, producing no injurious effect; on the contrary, some have considered the occurrence of bluish-green pus as a favorable omen, inasmuch as gangrene and septic complications were usually not observed in connection with green suppuration. Since the days when "good and laudable" pus was considered a good omen in the course of the healing process, green or blue pus has lost its fascination for the surgeon, particularly since recent experiments (Ledderhose, Bouchard) have shown, as already stated, that, in animals destitute of immunity (guinea pigs and rabbits), subcutaneous or intraperitoneal injections of recent cultures in bouillon caused the death of the animal in from twelve to thirty-six hours. In the case of the subcutaneous connective tissue an extensive inflammatory ædema and purulent infiltration of the tissue spaces, and in the case of the intraperitoneal injections a sero fibrinous or purulent peritonitis, is induced. The cultures can be recovered from the serum or purulent fluid in both localities, as well as from the blood and the various organs. These results follow the introduction of one cubic centimetre or more of the bouillon culture. The introduction of smaller quantities may only be followed by local disturbances (abscesses), but thereafter the animal becomes immune against the usual toxic dose for animals of its class. Immunity may also be brought about by the introduction of the toxic products of the bacillus in bouillon, the latter being sterilized.

An antagonism between this micro-organism and the bacillus of anthrax has been supposed to exist from the fact that animals inoculated with the latter are found to recover after inoculation with a pure culture of the Bacillus pyocyaneus (Bouchard, Charrin, and Guignard). This is probably due to the antidotal effects of the chemical products resulting from the proliferation of the bacillus (Woodhead and Wood), as shown by the fact that the same effect was produced if a sterilized culture of the saprophyte is introduced following the anthrax infection.\*

Injections of cultures of Gessard's bacillus into the veins of animals produced the most pronounced toxic symptoms. From forty-five to sixty cubic centimetres of a culture, from

<sup>\*</sup> Sternberg. Manual of Bacteriology.

two to three days old, introduced into the jugular vein of a dog produced death of the latter with characteristic symptoms, consisting of high fever, vomiting, and dejections of bloody fluid. Upon the death of the animal, section disclosed extensive hæmorrhagic and inflammatory conditions of the intestinal tract, together with subendocardial blood extravasations (Bergmann). Intravenous injections into the auricular veins of rabbits invariably produced death, even in relatively small doses (Charrin). Doses insufficient in amount to produce death usually induced paralysis in the posterior extremities, and albuminuria, the result of renal changes. In lethal cases a more acute course followed, characterized by fever, diarrhœa, and albuminuria. Intravenous injections are most pronounced in their effects; next comes subcutaneous and intraperitoneal inoculations. Exposure of the air-passages and of the intact gastro-intestinal mucous membrane to the action of the bacillus gave negative results.

Varying degrees of immunity and susceptibility are observed in different animals and in individual specimens of the same animal. For instance, some rabbits will rapidly perish from the usual toxic dose, while others remain alive after a much larger dose. Still others appear unaffected at first, but die after weeks or months of apparent health.

The later experiments of Bergmann would seem to show that neither progressive phlegmon nor sepsis occur with minimal doses of the culture of the Bacillus pyocyaneus. Even the most virulent cultures applied to open wounds have apparently but little effect. The effect in larger quantities, however, seems to be in direct proportion to the dosage. Even with larger doses of the bouillon cultures injected subcutaneously, while local abscesses and general toxic effects manifest themselves, the occurrence of progressive suppurative processes or of pyæmic metastases to remotely placed articulations, or to the internal organs, are not observed. In the cases in which abscesses are produced by subcutaneous injection of the bacillus the latter can be identified in the pus for a considerable time afterward and cultures made therefrom. The micro-organism, however, can not be identified in the surrounding tissues, nor does it appear to enter the circulation of the blood. When intravenous injections are employed, however, particularly in conjunction with an emulsion of sterilized lard, suppurative infarction in the lungs takes place. In addition to this, larger injections into the jugular veins of rabbits are followed, even in those instances in which rapid death occurs by the presence of the micro organism in all of the internal organs and in the blood as well. If, however, injections which are insufficient to produce death are given in a number of animals, and these killed at varying periods of time, it will be found that the bacillus will disappear, first from the arterial circulation, next from the lung tissue. following this from the liver and spleen, and last of all from the kidneys. They are found in large numbers in the urine and bile, thus suggesting that the liver and kidneys act as eliminators of the bacilli. This progressive elimination of the micro organism would seem to prove that no proliferation, but rather a decrease in the number of the bacilli, takes place. This occurs partly by destruc-

tion in the fluids of the body and partly by elimination through the organs above mentioned.

It would therefore appear that the picture presented of the behavior of animals under the influence of this saprophyte suggests rather an intoxication, either local or general, than symptoms resulting from an area mycosis. The fact that the effect is increased or diminished in proportion to the dosage, and the absence of advancing symptoms as well as evidences of proliferation of the bacillus in the tissues, recall the influence of irritating chemical agents upon the animal rather than the gradually progressive processes of disease based upon the advance of bacteria. This is further increased by the fact that the toxic products of the disease in bouillon cultures of the bacillus are not destroyed, although somewhat diminished by repeated attempts at sterilizing by heat at the boiling point. The removal of all corpuscular elements by filtration is equally inefficient with heat in eliminating the poisonous bacterial proteines, as Binhuer calls the albuminous portions of the bacterial cells which this observer located in the latter, and upon which the effects of the bacillus, notably the high temperature and inflammation, depend. It seems to be definitely settled that the toxic properties do not reside in the pyocyanin or the pigments generally, for the reason that even in large doses these are quite harmless. On the other hand, the bacterial proteins-which are obtained by scraping cultures grown upon a solid pabulum, such as potatoes, and dissolving these in weak alkaline solutions-are capable of producing the symptoms, even after heat sterilization and filtration, usually attributed to the presence of the bacillus in living cultures.

The fact should not be lost sight of, in considering the question of the toxic influence of cultures derived from the Bacillus pyocyaneus, that these are not conditions specifically related to or characteristic of this micro-organism. These symptoms of local irritation and general intoxication are common effects of bacterial infection from many sources.

There are numerous recorded observations of the presence of the Bacillus pyocyaneus under circumstances which would seem to suggest, with some degree of plausibility at least, that this micro-organism bore some ætiological relation to the conditions present. Thus it has been found in the pus from a suppurating otitis media (Gruber). It has been observed in septic peritonitis together with the Bacillus communis and other micro-organisms. It was found post-mortem in the hepatized lung of a child an hour and a half after death in conjunction with the Proteus vulgaris (Neumann). In a case which simulated typhus an eruption of bullæ occurred in the inguinal region in the third week. The blebs filled with a bluish serum, from which pure cultures of the Bacillus pyocyaneus were obtained (Oettinger). A rather interesting observation is made by Ehlers: Two children fell sick with diarrhœa, fever, albuminuria, and symptoms suggestive of typhus or cerebro-spinal meningitis. In one case an eruption of blebs occurred on the twelfth day, the contents of which were bluish in color. Pure cultures of the Bacillus pyocyaneus were obtained from these. In the other case

pure cultures of the same organism were obtained from the blood post-mortem. While at first sight some of these cases seem striking, yet it must be admitted that they are The ætiological relations between scarcely convincing. the bacillus found and the conditions present in any given case is always a difficult matter to establish. For instance, the natural habitat of the bacillus has been shown to be the skin of the patient himself.\* Green suppuration occurs with especial frequency about the axillary cavity, the gluteal furrow, and the inguinal fold (Muchsam). Eberth's researches have shown that the greenish-blue color imparted to the underclothing of some individuals depends upon the proliferation of this bacillus. It is a matter of common observation that the portions of the garments which come in contact with these localities are the site of these discolorations. This would explain the occurrence of the organism in the blebs in the inguinal region in Oettinger's case, in those following burns, and, in fact, in all the cases in which it has been found upon the integumentary surface. The fact that this organism is found in pure culture does not necessarily prove in any case that it was the true pathogenetic agent, for the latter may have easily escaped detection because of errors of inoculation, the absence of a proper culture media, etc. Gruber's observation is likewise open to criticism, for the tenacity of the Bucillus pyocyaneus when suspended in pus is well known, while the readiness with which certain other bacteria are inhibited in their growth or destroyed altogether by the presence of phagocytes should be borne in mind.

In considering the cases in which certain phenomena of a general character are recorded as having occurred in connection with the organism under consideration, several facts should be borne in mind. First the frequent occurrence of the bacillus upon the skin and presence of blue or green pus under circumstances of entirely undisturbed general health of the individual. Of the large number of cases of blue or green suppuration seen at the various clinics in the course of a year, I have yet to hear of a well-authenticated instance in which the nervous and febrile phenomena observed in both of the cases here recorded occurred. As to the discovery of the bacillus in the blood and internal organs post-mortem, this may be explained by the facility and rapidity with which saprophytic bacteria of both the skin and intestinal canal invade the tissues after death.

While, therefore, it is comparatively easy to account for the presence of the *Bacillus pyocyaneus* in the pus of middle-ear disease, in the blebs or blisters the result of burns, as well as those which occur as exanthemata, and in the blood and internal organs of those dying from symptoms resembling typhus and cerebro-spinal meningitis, and from which presence a pathogenic significance has been drawn, in all probability without due weight being given to all of the factors entering into the cases as they occurred, and the observations as they were made, it is difficult to explain the presence of the micro-organism in pure culture in the tissues of living patients, as occurred in the cases the histories of which have been given, without attributing to them a pathogenetic significance.

The possibility of some other micro-organism being mistaken for the one under discussion is, of course, always among the possibilities. Or, like the Bacillus coli communis, it may be that under certain circumstances the Bacillus pyocyaneus may assume pathogenetic properties in man not usually attributed to it.

In this connection the observations of H. C. Ernst are of interest. This writer discovered a bacillus in the fluid taken from a case of pericarditis which resembled that of blue or green pus in some respects, but which differed from the latter, as claimed by Ernst, in several important particulars. He claims that the micro-organism, which he identified and which he has called the Bacillus pyocyaneus pericarditidis, is a distinct variety of the bacillus of Gessard, and that therefore the assertion of the latter that there is but one blue-pus bacillus is unfounded.\* The pathogenesis of H. C. Ernst's bacillus appears to be essentially the same as that usually attributed to the bacillus of Gessard, save that a somewhat smaller dose suffices to produce the effect.

To sum up, therefore, it may be stated: 1. That the destructive and profoundly toxic effects which characterize the presence of the Bacillus pyocyaneus in the lower animals have not heretofore been observed to occur in man. 2. That where its presence has been discovered in connection with pathological conditions the pathogenetic significance of the organism has not been established, for the reason that heretofore there has not been placed upon record a single well-authenticated case in which the Bacillus pyocyaneus was present in pure culture in the living tissues of the patients. Its presence in the blebs of Oettinger's case of typhus offers no more significance than is offered in those cases in which it is found in the blebs following burns. 3. The utmost that any of the observers who have studied this organism have yet claimed is that it delays the healing process, particularly the formation of new integumentary covering to the granulations, and produces a slow, chronic, but not intense toxæmia.†

Viewed from this standpoint, the observations herewith recorded may be looked upon as somewhat unique, suggesting, at least, that although this organism has no special tendency to invade the living tissues, yet that, under certain yet unexplained conditions of growth or environment, they may become thus migratory and give rise, unless promptly followed up, to the most disastrous consequences. Or a bacillus similar to that of Gessard, as well as that claimed by H. C. Ernst, not distinguishable by means now at our command from that of green or blue pus, but possessing a

<sup>\*</sup> The origin of the bacillus of green or blue pus has recently become a subject of considerable interest to the surgeon. De Symmes investigated the condition of the atmospheric air in the operating room of Bergmann's clinic, and in several hundred plates and more than four thousand varieties of micro-organisms this bacillus was identified in but one instance. And this occurred at a time when a large number of cases of green suppuration were being dressed in the clinic. The constant employment of dressing materials made rigidly aseptic by exposure to heat above the thermal death point of the bacillus renders it very improbable that they convey the germ, since it is found to occur when such dressings are employed.

<sup>\*</sup> Ernst. Bacillus Pyocyaneus Pericarditidis. American Journal of the Medical Sciences, October, 1893.

<sup>+</sup> Schimmelbusch. Sammlung klinischer Vorträge, No. 62.

pathogenic importance not attributable to the latter, may have been the noxious and infective agent at work in these cases

The truth of the matter will probably be found in the statement that the world is but upon the threshold of bacteriological science, and that most remarkable revelations are yet to come. The cases herewith presented are offered with the hope of stimulating research and possibly identifying a special organism bearing an actiological relation to cases of rapidly progressive gangrene.

# A CASE OF INTRA-ABDOMINAL SARCOMA.\* By CHARLES PHELPS, M.D.

I PRESENT a specimen of tumor which I removed two weeks ago, and which was situated partly within and partly without the peritoneal cavity. A pelvic origin was excluded by gynæcological examination, but its exact location and character occasioned some differences of opinion.

The patient, a woman aged forty-two years, has had no serious illness at any time, and, with perhaps the exception of a single incident, her history affords no suggestion of the existence or development of the disease from which she suffered. Eighteen years ago she was startled by the sudden appearance of a tumor in the left abdominal region, followed by local pain and by vomiting after the ingestion of food. After three months this tumor disappeared. In October last she discovered the present tumor in the median abdominal line. Its advent was as sudden and unexpected as that of its predecessor, and occurred to her while she was standing at the washtub. She was admitted into St. Vincent's Hospital three weeks later. It was firm, irregular in outline, hard, and freely movable. At one point, to the right of the median line, it was adherent to the superficial tissues, and the skin was beginning to inflame. It was not tender, but occasioned pain when she moved about. She was able to retain only fluid food, and movements from the bowels were natural.

An operation was done on November 21st, four weeks after the patient's discovery of the tumor. It was found, on incision through the median line, that the growth was in greater part intraperitoneal, but involved the abdominal wall from within as far as the deep surface of the superficial fascia. The anterior portion was first removed as a flattened mass from the rectus sheath. The muscular planes were then pushed aside and the remaining portion was circumscribed by an incision through the peritonæum, after the rectus muscle and sheath had been cut through above and below. The omentum, which with the peritoneum was incorporated with the tumor, was cut on either side, adhesions to the transverse colon and small intestine were separated, and the entire mass, including implicated mesenteric glands, was enucleated from the mesentery. No portion was left behind. This necessitated a loss of peritonæum of about six by four inches. The wound was closed without difficulty, except that in its center the peritoneal edges could not be brought in contact. Recovery has been somewhat retarded by the formation of parietal abscesses, but has been otherwise uneventful.

Subsequent microscopic examination of a portion of the tu-

mor situated immediately behind the rectus sheath determined it to be in part a mixed-cell sarcoma and in part a fibro-sarcoma.

It seems probable that its origin was intraperitoneal, from the fact that its larger portion occupied that position, as well as from the further fact that the rectus sheath and muscle, though more or less infiltrated, had everywhere retained their general integrity of outline, which was hardly to be expected if they had constituted the elder site of disease.

It is at least possible that the tumor which so suddenly appeared and so rapidly disappeared eighteen years previously may have been only the beginning of this one which became evident in October last. This supposition is to some extent strengthened by the fact that this tumor, like the first, was developed from the left side. If such a lengthened period of quiescence is not to be assumed in the growth of a sarcoma, it is quite credible that a simple adenoid phlegmasia in the mesentery may have temporarily become prominent only to quickly subside, and at an indefinitely later period terminate in sarcomatous connectivetissue degeneration. Such a history would be not only of great interest in itself, but corroborative of our present belief in the necessity for the earliest practicable removal of all analogous as well as heterologous deposits. This is, however, only a speculative suggestion, as incapable of proof as of refutation.

#### A CASE OF

#### BILATERAL OVARIAN FIBRO-SARCOMA.\*

BY FREDERICK H. WIGGIN, M. D.

The comparative rarity of ovarian fibro-sarcoma (Schröder finding but ten out of six hundred, and Olshausen twelve out of two hundred and ninety-three ovarian growths) makes the specimens to which I desire to call your attention of interest.

On November 5th I was asked to see Mrs. J. R., forty-five years of age, whose history was as follows: She began to menstruate at ten years of age; it was painless and regular, of the monthly type. It diminished in quantity slightly before it ceased entirely last January. She has had three children, all of whom are alive, the youngest being twenty-one years of age. She has had two miscarriages—one sixteen years ago, the last three years ago.

Previous History.—Her health has always been good. Her present illness commenced with the cessation of menstruation last January. At that time she felt a fullness in her abdomen, and by that her attention was called to a tumor low down in the abdomen, of about the size of a hen's egg. This tumor has increased in size regularly, and of late rapidly. Four months ago she noticed the second tumor, which also increased in size gradually till within a short time. During the last few weeks she has lost flesh and strength rapidly, the urine has been scenty, and breathing has begun to be affected.

Physical Examination.—The patient is extremely emaciated; her breathing is short and shallow; her abdomen is enormously distended. Palpation reveals marked ascites. The lower part of her abdomen, as high as the umbilious, is filled by a nodular

<sup>\*</sup> Read before the Society of the Alumni of Bellevue Hospital, December 6, 1893.

<sup>\*</sup> Read before the Society of the Alumni of Bellevue Hospital, December 6, 1893.

tumor, divided into two parts by a deep sulcus. Vaginal examination reveals a hard, nodular tumor completely filling the pelvic roof; the cervix and uterine cavity are normal; the uterus is anteverted and crowded over to the left side. An operation was advised, and performed with the assistance of Dr. W. S. McLaren, of Litchfield, Conn., and Dr. Karrman, of North Woodbury, Conn. On opening the abdomen, a large amount of fluid escaped; the tumors immediately presented, and were found to be free from adhesions. They were removed without difficulty. The patient made a good recovery, her temperature and pulse becoming normal within forty-eight hours.

I am indebted for the microscopical examination and report to Dr. E. K. Dunham, of the Carnegie Laboratory.

55 WEST THIRTY-SIXTH STREET.

# SOME INTERESTING AND CURIOUS INCIDENTS IN THE HISTORY OF ANAL FISTULA,

INCLUDING IN IT THE ACCOUNT OF A FEW CELEBRATED PERSONS WHO WERE THE SUBJECTS OF IT.

BY WILLIAM BODENHAMER, M. D., LL. D.

The attention of the writer was called to this particular subject by reading an article in a late number of the New York Medical Record, copied from the Medical Press, upon the subject of the treatment of the Grand Monarque Louis XIV of France for an anal fistula, etc. The first sentence of the article alluded to is as follows: "It is not, perhaps, very extensively known that Louis XIV, of France, was one of the first to undergo the ordinary operation for rectal fistula—that is, of slitting up the fistulous tract with a bistoury."

The writer consequently, from these data, concluded to enlarge the subject somewhat, taking it for granted that it would not be distasteful to the profession, but would be both interesting and agreeable to medical readers generally to hear more of the history, both ancient and modern, of this very remarkable disease denominated fistula in ano—a disease, too, which claims so high a rate of antiquity. But before presenting the incidents mentioned the writer will, by way of introduction and for the better understanding of the subject, make some remarks upon the theory and the practice of the ancients and the moderns in relation to this very ancient disease.

It may here be observed as a singular fact that, by reading what has been written upon the subject of anal fistula by a few physicians and historians of the fifteenth, sixteenth, and seventeenth centuries, it would naturally be taken for granted that this affection, like leprosy, had always been considered incurable, and that the victims of it, for this and other reasons, had concealed their irremediable malady.

The celebrated John Astruct, in his Latin dissertation on fistula in ano, relates an interesting incident in relation to this disease. He says that for an age previous to 1687, the year in which Louis XIV was operated on, the fistula of the anus had almost sunk into oblivion, and was scarcely ever seen or heard of by physicians; not that the disease did not exist, but in consequence of a false delicacy in those who had it in not making it known; de-

spairing of any remedy, they preferred to conceal a disease which at that time was considered incurable. (*Dissertatio de Fistula Ani*, 12mo, Monspelii, 1718.)

But why anal fistula should have been considered incurable at the particular time mentioned is strange indeed, especially when we take into consideration the fact that no surgeons or physicians of any eminence, either ancient or modern, considered it incurable, but, on the contrary, declare that it always was amenable to proper treatment; indeed, there never was a time in the estimation of any intelligent and reputable surgeons of any period that anal fistula could not be cured unless it was complicated with some incurable disease. The question then may here be asked, Why did the subjects of this disease conceal it? Was it from a positive belief that it indeed was incurable? or was it simply from a false modesty to reveal it to the surgeon for treatment and cure ? It can scarcely be imagined, however, that a false delicacy could be carried so far as to prevent the patient from making application at once to the proper source for the relief of a more or less serious and always a most disagreeable disease, to which no reproach whatever could be attached. In close connection with this subject it may be proper just here to remark that all of the authors, not medical, cited in this article, when writing on anal fistula, omit the word anal, anus, or fundament, through delicacy, because either one of these terms, when used with the word fistula, at once locates the disease upon one of the so-called secret parts. The word fistula alone signifies a pipe or tube, but when used to represent a disease it means a pipelike sore-hence an anal fistula is a pipelike sore of the anus.

But, doubtless, a very considerable cause of the concealment of this disease by those patients was owing to the formidableness, the severity, and the danger attending some of the measures or methods of treating this disease, as devised and practiced at that period by some ignorant pretenders, that deterred the subjects of it from submitting to it; consequently those patients suffering from this affection might rather conceal and endure it than to submit to such treatment, especially as fear and pain could not then be annihilated as they now can by means of the sublime blessings of anæsthetics.

But during this very period the following able and distinguished modern surgeons and authors flourished, and their works were broadcast. They all declared that analistula was curable by either the knife or the ligature, and they proved it not only? by: words but by deeds also. In France was the celebrated surgeon Ambroise Parć, whose works were published in French, in Latin, and in English, and were widespread. (Euvres, liv. ii, chap. xxiii, folio, Lyon, 1641.)

M. Lemonnier was also a surgeon and author of France. (Traité de la fistule de l'anus, 12mo, Paris, 1641.)

Richard Wiseman, the celebrated English surgeon and author. (Seven Chirurgical Treatises, book iii, chap. v, p. 220, folio, London, 1796.)

Daniel Sennertus, another "able author. (Praxis medica, lib. v, cap. x, folio, Lugduni, 1650.)

The writer, for want of time and space, must omit giv-

ing the lengthened history of the celebrated Englishman John de Arderne, of the sixteenth century, who was distinguished for the successful treatment of anal fistula. (A Treatise on the Fistula in the Fundament. Translated from the Latin manuscript of John de Arderne, in the British Museum. By John Read, Esq., 8vo, London, 1588.)

And last, but not least, may be named among modern surgeons of this period Peter de Marchetti, the able and distinguished Italian professor of surgery and anatomy in the then celebrated university at Padua, who remarked before his death that he could affirm without vanity that he had successfully treated more than six hundred cases of fistula of the anus by the knife operation, sometimes combined with the actual or the potential cautery. (Observationum medico-chirurgicarum rariorum sylloge, cap. lxi, 4to, Amstelædami, 1665.)

So much for the able modern surgeons named, who with their works flourished about the time of Louis XIV, but who seemed at that particular time to have been forgotten or ignored.

And furthermore, from all the various data previously given, it would indeed seem to appear that prior to the close of the seventeenth century anal fistula had never been successfully treated, if treated at all, but seemed to have been lost sight of, forgotten, or ignored; and that the knowledge and the labors of the ancients regarding the pathogeny, the pathology, and the treatment of this disease had also shared the same fate; or that they had slept during the many dark centuries which intervened until, like magic, as it were, they were suddenly awakened, resurrected, and revivified from this state of oblivion and obscurity by the lucky surgeon M. Felix de Tassy, which the very opportune, the happy, and the fortuitous case of Louis XIV so amply afforded him. It will be perceived, however, that this surgeon did not in any particular whatever originate either the indication, the measures, or the modus operandi which he adopted in the treatment of the king's case, as some have intimated and would have us believe, but only revived at that particular time and place the ancient practice of completely dividing the fistulous passages by either the bistoury or the ligature.

But the ancients, whom the moderns of that period seemed to have lost sight of in the preceding dark ages, were not ignorant of this affection, as will now be briefly shown by giving some of the ancient treatment of anal fistula as practiced by a few of the most celebrated surgeons and physicians of antiquity, comparing it with that of the then moderns, and also with that of our own time.

Hippocrates, in the treatment of anal fistula, employed either the knife or the apolinose (ligature), according to the nature of the case. He plainly describes the method by apolinose and the manner of introducing it into the fistulous tracts. The ancient ligature used for this purpose was composed of hemp or flaxen thread, two or three double, to which were sometimes added a few horsehairs, which would not decay. Now, the principal indication which Hippocrates had in view in the treatment of this disease was to completely divide the fistulous sinuses either instantly with the knife or slowly by the ligature; and in tial cautery, or a combination of all these means. Upon

order to prevent the knife-incised parts from uniting or healing too soon, he used several kinds of caustics, whereas we of the present day, for the same and a better purpose, press pledgets of soft lint into the cavity so that the granulation and healing must take place at the bottom. (De fistulis liber.)

Galen, with the same indication in view as that of Hippocrates, treats this disease by incising the fistulous tracts with the syringotome. (Galeni Methodi medendi, lib. vi, cap. iv.)

Celsus, of all the ancients, understood more, perhaps, than any other the true nature or pathogeny and treatment of anal fistula. He used either the knife or the ligature, and advises that after the knife operation the lips of the incision should be secured by clamps or the edges of the wound should be united by sutures. He also sometimes adopted the method of the complete extirpation of the diseased or indurated parts by dissecting out the whole parietes of the fistulous passages.

Celsus also minutely describes the method by ligature, and says that it is slow, yet free from pain; he, however, only proposes the ligature for blind external fistulæ. The following are his directions for the introduction and the management of the ligature in such peculiar cases. He says: "The specillum (probe) being introduced into the fistula, an incision should be made through the skin on the extremity of it; then from this new aperture the probe should be drawn out with the ligature attached to its distal end, perforated for that purpose; then the ligature should be seized and its two ends tied, so that the skin over the fistula may not be too tensely held; the thread should be double or triple, and so twisted that it may form one ligature. In the meantime the patient may attend to his ordinary business; he may walk, bathe, and take his food as if nothing were the matter." (De medicina, lib. vii, cap. iv.)

Albucasis approved of either the knife or the ligature in the treatment of anal fistula. (De chirurgia, lib. ii, cap. lxxx, folio, Argentorati, 1532.)

Avicenna employed the ligature for the treatment of anal fistula, and preferred for this purpose the twisted hairs of some animals, as they were not subject to decay. (Canonis medicinæ, lib. iii, cap. xvii, folio, Lovanii, 1658.) This was a wise choice of Avicenna's, so far as the durability of the ligature was concerned, but hair as a ligature has other valuable qualities-it is aseptic, it does not absorb, and it is less irritating. Hence it is far superior as a ligature to either hemp, flax, or silk.

The writer will now give some of the empirical treatment of anal fistula. It must first, however, be observed that the indurations and callosities consequent upon chronic inflammation, by which fistulous passages and abscesses are usually surrounded, were anciently considered malignant alterations of structure, and that they absolutely required a complete removal before a cure could be effected. These erroneous opinions led to the adoption of some of the most violent and barbarous methods, such as the complete extirpation of all the diseased or callous parts by the knife, or a destruction of them by the actual or the potenthis same subject the able English surgeon, Mr. Pott, when speaking of the ignorance of some of the early modern surgeons, says: "Imagining this callosity to be a diseased alteration made in the very structure of the parts, had no conception that it could be cured by any means but by removal by cutting instruments or by destruction with escharotics, and therefore they immediately attacked it with the knife or caustic in order to accomplish one of these ends; and very terrible work, by their own accounts, they often made before they did accomplish it." (Chirurgical Works, edited by Sir James Earle, vol. ii, p. 203, 8vo, Philadelphia, 1818.)

It was this false notion that led Albucasis, Jean de Vigo, Durand, Sacchi, and Severinus to apply the red-hot iron to the parts after they had previously been laid open with the knife. It was this same error that induced Guido Cauliaco to make his incisions with a red-hot bistoury introduced on a grooved director. And it was the same erroneous opinion which caused Leonidas to carefully remove all the callosities by means of a forceps, a knife, and a peculiar speculum.

Turundæ, or tents, were also used in treating anal fistula; they were made of different materials, corresponding in size to that of the fistulous passages. These tents were then charged or imbued with various caustics and pushed into the sinuses, and their size daily increased until the passages were entirely destroyed.

Fabricius, ab Aquapendente, recommends the tent method of treating anal fistula. He also uses the ligature in the same disease, and says: "We, to draw the ligature the tighter, put in a little turn stick, about the middle of the ligature, and, by turning this about, the ligature becomes twisted up extremely tight. (De fistula ani, 12mo, Lugduni, 1592.)

M. Dionis, in his surgical work, speaks of a noted quack who treated anal fistula by tents. He says: "There lived in Paris in 1700 one Le Moyne, who acquired a great reputation for the cure of anal fistula. His method consisted in the use of caustics-that is to say, with a corrosive unguent, with which he covered a small tent which he thrust into the sinus, by which he daily, little by little, consumed the circumference, taking care to enlarge the tent daily, so that by the widening of the fistula he discovered its bottom. If he found there any callosity, he corroded it with his ointment, which also served to destroy the coney burrows (sinuses), and at last, with patience, he cured many. This man died old and rich, by reason he made his patients pay very well for their cure, in which he was in the right, for they value things no otherwise than in proportion to the sum which they cost. Those who were affrighted at the thoughts of the knife and the scissors threw themselves into his hands, and though the number of rascally pretend ers is very great, they never yet want practice." d'opérations de chirurgie démonstrées au jardin du roi. Par De la Faye. Tome i, p. 411, 8vo, Paris, 1782.)

Strong solutions of the various caustics were also used at this early period in the treatment of anal fistula. They were injected into the fistulous tracts for the purpose of destroying the induration or callosity.

The writer has now briefly shown that the ancients were not ignorant of the nature, cause, and treatment of anal fistula, but understood them well. They possessed all the indications in the treatment of this disease, as well as the numerous measures and methods of putting them into execution. They had incision and excision with the bistoury; they had the ligature; and they also had cauterization in all its many forms; indeed, we are indebted to them for almost all we know upon the subject of anal fistula. It may then be asked, What more is known of this disease at the present time, or what more is done to cure it than that which we find in the works of the ancients named? whose works, too, seem to be as durable as time is lasting. But, regarding other diseases even, as well as this. it may be truthfully answered that we of the present wonderful age of revolution and progress have many invaluable aids to surgery in the perfection of new and appropriate instruments and various valuable appliances, as well as entirely new methods of operating which the ancients had not, our armamentarium being much more complete and suitable; we also have the blessed annihilator of pain and antisepsis, the two most powerful agents which render such invaluable service to the success of surgery; indeed, they embolden and inspire with confidence the surgeon to attack viscera or parts which heretofore would have been shunned. or would have been attacked with the gravest apprehension. We also have many new and most valuable therapeutic remedies, and also many successful sanitary measures for the prevention of disease which the ancients had not.

It is said, by the by, that ancient surgery was without drainage and drainage-tubes, which are so essentially necessary in many surgical cases, they being the inventions of recent times. But it ought to be known that Hippocrates himself, twenty-three centuries ago, used and recommended drainage by the use of tubes in deep seated mammary abscesses. (Hippocratis opera omnia grace et latine, ab Anutio Foësio. De ratione victus in morbis acutis liber. Lib. ii et lib. iii, tome i, pp. 461 et 487, folio, Genevæ, 1657.)

Now, from all that has been shown of the knowledge and the practice of the ancients with regard to anal fistula, the conclusion can readily be drawn that, with respect to their practice in some other diseases, they might be equally expert. We, however, are too apt, in this marvelous age of progress, to ignore the ancients and to claim for ourselves the whole merit of the present highly improved state of medical science, closing our eyes upon the fact that we still have much to learn in regard to real substantial and permanent principles, theory, and practice, to be entirely out of sight and out of mind of the ancients; indeed, we are not yet too many steps in advance of them-steps which they made many centuries before us, and made, too, under far less favorable and advantageous circumstances. Then let us not despise or undervalue in the least what has been done and written by the ancients upon the subject of anal fistula, as well as upon that of other diseases; neither should we ever forget or lose sight of those noble Greek, Roman. and Arabian physicians, the representatives of three of the most intellectual nations of mankind, who as pioneers first discovered the correct road and blazed it as they passed through the wilderness and subsequently made no inconsiderable improvement in it; hence no small degree of praise should be withheld from them.

Now, for instance, it is in this manner that one generation of medical men, in the active exercise of their faculties, acquires a certain amount of knowledge and skill; this is transmitted to the next generation, and it in turn adds its proportion and so on, each generation in its turn accepting knowledge of its progenitors and transmitting with its own acquisitions the sum total to its successors. To repeat, let us not then aid in destroying the stepping stones by which we of the present generation have attained the noble height we now occupy.

The writer, in concluding this part of the subject, will respectfully remark that fistula ani, when not connected with morbid conditions of the lungs, intestines, or other viscera, equally incurable and fatal, may be regarded as one of the most simple and most satisfactory subjects of surgical practice; indeed, there is no disease more amenable to the treatment of the present day than anal fistula, it deriving nearly all its difficulties and dangers from diseases that complicate or succeed it.

A Few Noted Subjects of Anal Fistula.—The earliest notable case of this disease on record, so far as known to the writer, is that of an eminent lawyer and a Christian named Innocent, who in 388 resided at Carthage, which was the then famous African city of antiquity. The original account of this unique case is given in full and vouched for by that able and devout prelate St. Augustine, who was also present and witnessed the event, the whole account of which he gives in his celebrated work, De civ. Dei, lib. xxii, cap, viii. The writer, however, being unable to find a copy of this work of St. Augustine, will give the account of the case as it is reported in the life of St. Augustine by the Rev. Alban Butler, D. D., which is as follows: "St. Augustine landed at Carthage about September in 388, and there lodged for some time in the house of a virtuous lawver named Innocent, and was witness to his miraculous cure of a dangerous fistula, while the best surgeons of Carthage and Alexandria were preparing to form a dangerous incision, a sinus which was deeper than the rest of the sore having escaped several operations which he had already undergone. The patient prayed with many tears that God would mercifully preserve him from this danger. Saturninus, Bishop of Uzalis, Aurelius, who was afterward Bishop of Carthage, and several other pious clergymen, who often visited him during his illness, were themselves present, falling on their knees, joined him in his devout prayer. St. Augustine was also one of the company and relates how the surgeons, coming the next day, he that was to perform the operation took off the bandages and, to the astonishment of all who had seen the wound before, found it entirely healed and covered with a very firm scar" (Lives of the Saints, vol. viii, p. 517 et seq., imp. 8vo, New York, 1864). Daniel Sennertus, in his Latin treatise on medicine, also very briefly alludes to this case, without, however, giving the name of the patient. He says: "There is extant in St. Augustine's work, De civ. Dei, the account of a most miraculous cure by devout prayers of a fistula in

ano, which is well worth the reading "(Praxis medica, lib. v, cap. x, folio, Lugduni, 1650). M. Velpeau, in his great surgical treatise, also gives the account of this case, but says that the patient was Pope Innocent; but this is certainly an error of his and may have occurred from the similarity of names.

The Case of Henry V of England .- It is said that King Henry V died of an anal fistula on the 31st day of August, 1422, in the thirty fourth year of his age and tenth of his reign. The great historian Hume, on this event, says: "But the glory of Henry, when it had nearly reached the summit, was stopped short by the hand of Nature, and all his mighty projects vanished into smoke. He was seized with a fistula, a malady which the surgeons at that time had not skill enough to cure; and he was at last sensible that his distemper was mortal and that his end was approaching. He sent for his brother, the Duke of Bedford, the Earl of Warwick, and a few noblemen more whom he had honored with his friendship, and he delivered to them, in great tranquillity, his last will with regard to the government of his kingdom and family." (The History of England, vol. i, chap. xix, p. 418, imp. 8vo, Philadelphia,

The historian does not intimate whether either radical or palliative treatment had been employed in the case of the king, but says, plainly enough, that the surgeons of that period had not skill enough to cure an anal fistula, the disease of which the king died. This stigma upon the escutcheon of surgery at that time, if really and fairly deserved, plainly indicated that anal fistula then was the opprobrium medicum.

The French King's Case by Shakespeare.—Shakespeare has rendered anal fistula quite notorious by making it a very important feature in his play, All's Well that Ends Well. To what particular French king Shakespeare alludes must be largely left to conjecture, as he could not have had reference to the case of the Grand Monarque Louis XIV, who was treated in 1687 for the same disease. The play, however, is said to have been written in 1606, just eighty-one years previously, and Shakespeare died in 1616, ten years after. But the French king in the play may have been one of Shakespeare's fictitious characters, the sole invention of his extraordinarily fertile genius. It will be perceived that in this play the surgeons of the time, like in the case of Henry V, meet with a similar implied stigma, but they doubtless survived it.

A small part only of the prelude of the play is given:

All's Well that Ends Well.

Act 1. Scene 1.

Countess. What hope is there of his Majesty's amendment !

Lafeu. He hath abandoned his physicians, madam, under whose practices he has persecuted time with hope, and finds no other advantage in the process but only the losing of hope by time.

Countess. This young gentlewoman had a father (oh, that had! how sad a passage 'tis!) whose skill was almost as great as his honesty; had it stretched so far, would have

made nature immortal, and death should have play for lack of work. Would for the king's sake he were living! I think it would be the death of the king's disease.

Lafeu. How called you the man you speak of, madam?

Countess. He was famous, sir, in his profession, and it was his great right to be so: Gerard de Narbon.

Lafeu. He was excellent, indeed, madam; the king very lately spoke of him admiringly and mourningly; he was skillful enough to have lived still, if knowledge could be set up against mortality.

Bertram. What is it, my good lord, the king languishes of?

Lafeu. A fistula, my lord.

Bertram. I heard not of it before.

Lafeu. I would it were not notorious. Was this gentlewoman the daughter of Gerard de Narbon?

Countess. His sole child, my lord; and bequeathed to my overlooking.

Case of the Grand Monarque Louis XIV.—This was a very remarkable case in several respects—not, however, that there was anything extraordinary either in the disease itself or in the treatment; these were all of the most simple character; but its remarkableness was doubtless owing to a general lack of information regarding the true nature and character of the disease, which was then looked upon as something entirely new and marvelous; to the emotional and impressive character of the people; and to the distinguished patient himself and his unwillingness to submit at once to proper and rational treatment, instead of spending precious time in having the numerous empirical remedies and methods tested upon others.

In confirmation of what has just been said, it may be proper to remark here, as a notorious fact, that after the king had been operated on many of his courtiers and others suddenly pretended to be afflicted with the same disease; indeed, it became the bon ton, and every one wanted to have the king's disease—maladie du roi—as it was then designated, and all insisted upon being operated on as the king had been.

M. Dionis alludes to the same subject. He says: "Fistula in ano seems more frequent now than formerly; we every day hear of operations performed on such persons as did not before seem afflicted with it. It is a disease grown into fashion since that which his Majesty Louis XIV had, and on which the surgeons were forced to perform the operation in order to its cure. Several of those who before that time carefully concealed their having it are now not ashamed to publish it, and some courtiers have even chosen Versailles for the place where they will undergo this operation, because the king would there be informed of all the circumstances of their indisposition. I have seen above thirty who desired to have the operation performed, and whose folly was so great that they seemed angry when they were assured that they did not at all need it." (Op. cit., tome i, p. 406.)

There is a case parallel to the preceding, which is related by the elder Pliny, author of the Natural History, who says: "In the reign of Tiberius Cæsar the colic first showed itself; nor did one man in Rome ever complain of this disease till the emperor himself had been severely at-

tacked with it." (Natura historiarum, lib. xxv, cap. i, folio, Hagæ, 1518.)

The celebrated Madame de Sévigné, in some of her letters written during the excitement consequent upon the king's disease, and the cure of it by M. Felix, says in one of her letters: "The king had been operated on for a fistula on the 18th of November, 1687, by M. Felix de Tassy, his first surgeon. The king supported the operation with the greatest courage." In another letter, dated Paris, January 15, 1688, she says: "We can not thank God enough for the perfect health of the king, now relieved from his disease. The public rejoicings which take place are a proof of the sincere grief which his illness had occasioned among his people." In another letter Madame de Sévigné writes to her daughter, Madame de Gregnan, in which she speaks of the king's surgeon, M. Felix. She says: "The Abbot Bigorre writes to me that M. de Niel fell the other day, while standing in the room of the king, and received a severe contusion. M. Felix, in bleeding him, cut an artery. The grand operation was instantly needed. What does M. de Gregnan think of it? For my part, I do not know who is the more to be pitied of both parties. Only think of a first surgeon to the king who cuts an artery!"

The history of the Grand Monarque's case before, at and after the operation will now be given as recorded in the excellent surgical treatise of M. Dionis, which is as follows: "In the year 1686 there arose near the king's anus a small tumor inclining toward the perinæum; it was neither inflamed nor very painful; it grew slowly, and after ripening, broke of itself, by reason that the king would not suffer M. Felix, his principal chirurgeon, to open it as he proposed. This small abscess was attended with the ordinary consequences of those not sufficiently opened to admit the application of remedies to the bottom of the cavity; there was only a small orifice through which the matter ran; it continued to suppurate, and at last became fistulous. The sole way left of curing it was by manual operation, but the great can not always be brought to yield to it. A thousand persons proposed remedies which they pretended to be infallible, and some of them, which were concluded to be the best, were tried, but none of them succeeded. His Majesty was told that the waters of Barège were excellent in those cases, and it was also reported that he would go to the waters, but before taking the journey he thought fit to try them on several patients; four persons were found who were afflicted with the same disease, and sent to Barège at the king's expense, under the direction of M. Gervais, chirurgeon in ordinary to his Majesty; he made the necessary injections of this water into their fistulæ for a considerable time, and used the proper means for their cure, and at last brought them back as far advanced toward that end as when they first went thither. A woman reported at court that, going to the waters of Bourbon, in order to be cured of a particular disease, she was by the use of them cured of a fistula, which she had before she went thither. One of the king's chirurgeons was sent to Bourbon with four other patients, who returned in the same condition they went,

"A Jacobin friar, applying to M. Louvoy, told him that

he had a water with which he cured all fistulæ; another boasted of a never-failing ointment, and yet others proposed different remedies, alleging the cures which they pretended to have done. That minister, determining to neglect no means in order to the procuring a restoration of a health so important as that of the king, caused several chambers to be furnished, in which he placed persons afflicted with fistulæ, and caused them to be treated pursuant to the several methods of the boasting pretenders to cure them in the presence of M. Felix. A year was spent in these various essays, and not one patient cured. M. Bessière, who examined the indisposition, being asked his thoughts by the king, freely answered his Majesty that all the remedies in the world would prove vain without manual operation.

"At last the king, to whom M. Louvoy and M. Felix gave an account of what had passed, seeing no hopes of being cured otherwise than by operation, on which M. Felix continually insisted, determined for it; he delayed it till his return from Fontainebleau, and one morning had it performed when nothing of the nature was suspected by the courtiers, who, going to attend the king's levee, were informed that he had undergone the operation, and resolutely suffered all the incisions which M. Felix thought proper to be performed.

"This happened on the 18th of November, 1687. M. Felix, to whom the king had left the liberty of appointing what chirurgeons he pleased to assist him, chose M. Bessière, who was accordingly present at this operation, where besides were only M. Louvoy and the physicians, Dr. Daquin and Dr. Fagon. The cicatrizing was well managed, and the king perfectly cured. His Majesty royally recompensed all those who had rendered him service while under this indisposition; he gave to M. Felix fifty thousand crowns; M. Daquin, one hundred thousand livres; M. Fagon, twenty-four thousand livres; M. Bessière, forty thousand livres; and to each of his apothecaries, in number four, twelve thousand livres; and to one Raye, M Felix's apprentice, four hundred pistoles." (Cours d'opérations de chirurgie demonstrées au jardin du roi. Par De la Faye, tome i, p. 419, 8vo, Paris, 1782.)

#### Estimated Value of the Fees in United States Coin.

M. Felix received 50,000 crowns	\$30,000
Dr. Daquin " 100,000 livres	20,000
Dr. Fagon " 24,000 "	5,000
M. Bessière " 40,000 "	7,500
Four apothecaries (each 12,000 livres, \$2,500).	10,000
M. Raye (apprentice to M. Felix) 400 pistoles.	1,000

The writer will now close the case of the Grand Monarque with the remark that he proved himself to have been both grand and royal by the gracious and the liberal manner he displayed in the remuneration of his faithful medical attendants. He will also further add in conclusion the remarks upon the same subject of a writer in a very old number of the London Medico-chirurgical Review, which are as follows: "These were royal days for surgeons. The

fee which the operator on the Grand Monarque, M. Felix, pocketed was six thousand pounds. The name of this gentleman is emblematic of the palmy days of surgery in which he had the luck of flourishing. If an operator now receives a thousand pounds for giving sight to one of our millionaires he is thought a marvelously fortunate fellow."

184 Central Avenue, New Rochelle, N. Y., December 6, 1893

# NOTES ON THE FREQUENCY OF THE BATTLEDORE PLACENTA. By T. RIDGWAY BARKER, M.D., PHILADELPHIA.

While placenta prævia and succenturiata are of vastly more importance, both physiologically and pathologically, than the variety I have chosen as the subject of this article, from the grave complications that are likely to arise in their management, yet a study of the battledore may not, perhaps, be wholly devoid of interest.

In many of the standard text-books of to-day little if anything is said on this subject, which would lead one to suppose it was therefore of very infrequent occurrence.

This, to judge from my experience, is quite incorrect, as the report of a series of eighty unselected cases met with in practice goes to prove.

Until quite recently I gave the subject but little consideration, simply examining the placenta after every confinement to see that it had come away in toto without paying any particular attention as to peculiarity of shape or size.

This will account for the comparatively small number of cases reported. Since adopting the plan of making full notes of cases of confinement I have met with a series of six cases which naturally aroused my interest and led me to investigate the subject.

The cause or causes which induce this peculiar form of placenta are but imperfectly understood. That the chorionic villi on one side of the decidua serotina have failed to undergo the usual development every one is prepared to admit. In this way we can readily account for the insertion of the umbilical cord out on the periphery; but when we ask ourselves what occasions this imperfect development the problem is not so easy of solution. The thought has suggested itself to me that perhaps the site selected by the allantois for the attachment and growth of this fœtal organ may have considerable to do with the shape which it ultimately assumes.

If the allantois should come in contact with the chorion at a point abnormally near one or other of the Falloppian tubes or in the neighborhood of the fundus of the uterus and the space prove insufficient for the development of a circular placenta, the villi would undergo atrophy as in other parts of the uterine cavity, and the placenta would be one-sided with the cord on the margin.

The law of accommodation would then operate and an increased growth occur in the opposite direction, thus giving rise to the typical battledore variety of placenta. This view, I am prepared to admit, is based on theory rather than experimental research, and hence further study will be

necessary before we can arrive at any satisfactory conclusion, yet the facts would at least seem to bear out the theory. As to the frequency of this condition, my report shows that of eighty cases of confinement where delivery took place at full term the battledore placenta was present in thirty.

Of this number, nineteen were thirty years of age or under, while nine were under forty. The youngest female was fifteen years old, the oldest thirty eight years. As to the number of births in each case presenting this peculiarity of afterbirth we find the following: There were nine primiparæ and twenty multiparæ. Of the latter group, seventeen had had from two to five children.

One had had eight and one eleven. In one instance of twins there were two placents, both battledore. By this comparison of groups and classes we notice that this freak of Nature, as it were, occurs in primiparse as well as multiparse. With regard to the relative frequency we can form no opinion, owing to the limited data.

Moreover, we learn that neither age nor the number of pregnancies has any predominating influence. The same is likewise true with regard to the health and nationality of the patient. The sex of the infant renders no assistance in our efforts to solve the problem any more than do the other facts already mentioned, for in these eighty cases reported there were forty-two male and forty female infants.

Among the thirty cases of battledore placenta, fifteen were in cases of male and fifteen in cases of female children.

THE

### NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 10, 1894.

THE ALLEGED ANTAGONISM OF TOBACCO AND "ENGLISH CHOLERA"

In October, 1893, the Greenwich Workhouse, near London, suffered from an epidemic of choleraic diarrhœa, or "cholerine," that produced fatal results in eleven cases. The total number of cases was not far from two hundred and fifty. The disease was by many considered to be an outbreak of genuine Asiatic cholera, while others chose to denominate it "English cholera." The British Medical Journal for December 23d contains a special report that is positive in its denial that the attack was Asiatic in character. An examination was made, by order of the Local Government Board, by Dr. Klein and Dr. Bulstrode, and the results were made public on December 12th at an adjourned coroner's inquest. The testimony of the experts tended to show that the disease was an infectious diarrhea such as occurs during cholera years, but lacks the severity of true cholera. The bacteriological researches made disclosed no Koch's bacillus in any case. Dr. Klein stated that he had obtained, by cultivations from the intestinal discharges or contents, a new bacillus of the Proteus group. This microbe was not found in the well-water of the workhouse, which water was beyond doubt the cause of much of the sickness. That water could not have been the sole cause or the primum agens, because there were persons taken sick outside the workhouse who had had no access to that water,

From a London letter to the American Practitioner we quote the following paragraph that has an interesting account of the alleged antidotal influence of tobacco against this form of infection:

"With regard to an outbreak of cholera at the Greenwich Workhouse, it is said that it is very noticeable that male inmates who had been great smokers or who had been in the habit of chewing tobacco had passed unscathed through the epidemic. Nearly every adult male in the workhouse was or had been a smoker, and the statistics of the epidemic show that only eighty-three males had been attacked as compared with one hundred and sixty females. Generally speaking, the males' attacks were of a mild nature. There were several old Irish women in the workhouse who smoked before their admission (and now when they could manage it), and it is stated that not one of them had been attacked. The investigation which has been held leads Dr. Burney, the senior medical officer of the institution, to believe that the epidemic must have been caused by the water."

#### MINOR PARAGRAPHS.

PRECIPITATE DELIVERY.

Dr. Gabriel Gorin reports a case in the Annales de la Société medico-chirurgicale de Liége, which presents several features that are interesting from a medico-legal point of view. The patient, a multipara, in what was supposed to be the eighth month of pregnancy, sent for the accoucheur on account of pain. On examination, the os was found dilatable, but the bag of waters did not present during the pains. Three days later he was sent for again, when digital examination disclosed the os dilated to the size of a five-franc piece. The membranes were intact, the presentation was normal, but the pains were far apart and feeble. The woman was in good condition. She felt as if she must go to stool, and asked the physician to step into the other room. As an examination had been made but a few moments before, the attendant thought there could be no impropriety in allowing her to use the vessel. She was no more than seated on the commode when she had what she supposed to be an evacuation of the bowels. It was urged that she get back into bed, but she remained for about a minute, when it was discovered that the infant had been born and was lying head downward in the water, apparently dead Artificial respiration was resorted to, with the result of breathing being established in a short time. During the day there was hæmorrhage from the infant's nose, and its death ensued in the evening. An autopsy was not allowed, so it could not be made out whether death had been caused by fracture of the skull from the fall or not. The author had never heard of a case before where a patient was delivered of a child so near term without being aware of the fact, provided she was in her right mind. Insane patients may have such an accident, but it is not easy to understand, says M. Gorin, how extrusion of a full grown fœtus can take place without the knowledge of a sane mother. The circumstances of the case were such that no criminal intent could be laid to the woman, for she was acting under the direction of the doctor, and he, from his description of the case, could not be deemed guilty of culpable negligence. There was no doubt, though, that the death of the child was caused by its being precipitated forcibly into the vessel of water and being left there for some moments. That such accidents may happen to multiparous patients should be taken into consideration when, if ever, they are dealt with medico-legally. It is very easy to see how, under like circumstances, a child might be plunged upon the floor or expelled into a water-closet vault without any criminal intention on the part of the woman.

#### THE CLINICAL EFFECTS OF HYOSCINE HYDROBROMIDE.

THE January number of the Practitioner contains the report of the clinical experiments of Gordon Sharp, M. B., with this .drug. Although hyoscine, he says, is an isomer of atropine and hyoscyamine, it is generally believed to differ widely from them in its physiological effects. It was from the reports previously published of its beneficial action as a motor calmative, cerebral sedutive, and hypnotic in delirium that the author was led to make a thorough test of the drug. It was used hypodermically in cases of delirium tremens and in others for sleeplessness. In one of the delirium cases the effect was to reduce the large movements to a constant jerking of the extremities. There was paralysis of the muscles of deglutition, and the pulse and the movements of respiration were increased to such an extent that sleep was impossible. The pupils were widely dilated, with the eyes wide open. For a time the patient was in a comatose condition, but finally came out from under the specially mentioned or enumerated herein, are hereby trans-

influence of the medicine. A mixture of chloral and potassium bromide was given to produce sleep and quiet nervousness. In another case of delirium the author was satisfied that death was hastened by the great stimulation of the circulation and of the respiratory center. In a case of anemia, where everything had been tried to correct the headache and sleeplessness, a dose of hyoscine was given. It produced delirium so great as to alarm the attendants. There was convulsive jerking of the limbs, with extreme dryness of the throat, but without the slightest hypnotic effect. The author has decided that hyoscine differs but little in its action from atropine, and thinks that, until more is known of its chemistry, pharmacology, and clinical effect, it can hardly be recommended as a safe hypnotic.

#### THE BILL TO ABOLISH THE NEW YORK STATE COMMISSION IN LUNACY.

ELSEWHERE in this issue we print the text of Assembly bill No. 458, which aims to abolish the Commission in Lunacy, and confer upon a committee of the State Board of Charitiesreally upon the secretary of such a committee-the work of supervising the care of the insane in the State institutions. The purport of the bill is a good one, but it has been drawn very hastily, and ought to be thoroughly revised before being made the subject of debate in the Assembly.

#### ITEMS, ETC.

An Act to create a State Committee in Lunacy in the State Board of Charities, and to Abolish the State Commission in Lunacy.—The following is the text of Assembly bill No. 458, introduced by Mr. Glenn on the 2d inst.:

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

Section 1. Within ten days after the passage of this act the State Board of Charities shall, at a meeting called for that purpose, elect, by ballot, three members of its own body, who shall serve without compensation, and who shall constitute the State Committee of said board thereafter. At each annual meeting said board shall elect three members of said committee for the ensuing year. Said State Board of Charities shall appoint a secretary of said committee, who shall be known and designated as the State commissioner in lunacy, and who shall be a reputable physician, a citizen of the State, and a graduate of a legally chartered medical college, having been in the actual practice of his profession at least ten years, and who has competent knowledge of the treatment of the insane and the management of institutions for their care and custody. He shall receive a salary of five thousand dollars per annum, and one thousand dollars in lieu of his traveling and other incidental expenses. The said committee shall elect its own chairman.

SEC. 2. The said committee in lunacy is empowered and required to execute, through itself or its secretary, all the provisions of this act which pertain to its office; and shall direct its secretary accordingly, and shall also, with the consent of the board, make such other rules and regulations for its own government and that of its secretary as are not inconsistent with the provisions of this act, but said committee shall, at all times, be subject to the authority and control of the State Board of Charities.

SEC. 3. All the powers and duties conferred upon the State Commission in Lunacy by chapter two hundred and seventythree, laws of eighteen hundred and ninety, and chapter two hundred and fourteen, laws of eighteen hundred and ninetythree, or acts amendatory thereof, or by any other act-not ferred to, and conferred upon, the State Committee in Lunacy and its secretary, created by the first section of this act; and the State Commission in Lunacy is hereby abolished.

SEC. 4. It shall be the duty of the State Commission in Lunacy to transfer to the State Committee in Lunacy, on the written request of the chairman of such committee, all records, papers, books, office furniture, and other property, of whatever name or nature, belonging to the State and in its possession.

SEC. 5. The said committee shall be provided by the proper authorities with suitable accommodations in the State capitol for its office, where it shall hold its meetings as often as once in three months, the time for such meetings being fixed by the committee; additional meetings may be held at other times and places as the exigencies of the service may require. The committee is authorized to employ such number of clerks as it may deem necessary, but the total cost of such clerical service shall not exceed four thousand dollars in one year.

SEC. 6. This act shall take effect immediately.

The Medico-legal Society.—The programme for the next meeting, on Wednesday evening, the 14th inst., includes the following titles of papers: The Operation of the Lunacy Law of Pennsylvania, by Dr. Thomas G. Morton; The Railway Surgeon and the Law, by Clark Bell, Esq.; and Criminal Anthropology, by Sir Frederic Bateman, M. D., of England.

Dr. John S. Billings, of the Army, according to the Boston Medical and Surgical Journal, has been elected an honorary member of the Royal Academy of Medicine of Belgium, also a member of the International Statistical Institute, which has its headquarters in Rome.

The Society of Medical Jurisprudence.—At the next meeting, on Monday evening, the 12th inst., Dr. Landon Carter Gray will read a paper entitled What shall we do with those Turbulent Lunatics called Cranks?

Medical Society of the State of New York.—Dr. George H. Fox, of New York, has been elected President for the ensuing year.

The Death of Professor Theodor Billroth, the great Vienna surgeon, is announced as having taken place on Tuesday of this week. He was in his sixty-fifth year.

#### Society Meetings for the Coming Week:

Monday, February 12th: New York Academy of Medicine (Section in General Surgery); New York Academy of Sciences (Section in Chemistry and Technology); Society of Medical Jurisprudence, New York; New York Medico-historical Society (private—anniversary); New York Ophthalmological Society (private); Lenox Medical and Surgical Society (private), New York; Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

Tuesday, February 13th: New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Delaware (semi-annual) and Rensselaer, N. Y.; Newark, N. J., Medical Association; Trenton, N. J., Medical Association (private); Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Baltimore Gynacological and Obstetrical Society; Practitioners' Club, Richmond, Ky.

WEDNESDAY, February 14th: American Microscopical Society of the City of New York; Metropolitan Medical Society (private), New York; New York Pathological Society; New York Surgical Society; Medico-legal Society, New York; Medical Society of the County of Albany, N. Y.; Pittsfield, Mass., Medical Association (private); Franklin, Mass., District Medical Society (quarterly—Greenfield); Philadelphia County Medical Society.

THURSDAY, February 15th: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, February 16th: New York Academy of Medicine (Section in Neurology); Baltimore Clinical Society; Chicago Gynæcological Society.

Saturday, February 17th: Clinical Society of the New York Post-graduate Medical School and Hospital,

#### Answers to Correspondents:

No. 421.—There is such a school (in the sense of a sect). We are under the impression that it has a teaching institution somewhere in Indiana, but we are not sure.

No. 422.—In certain cases it may be advisable to wait until the effect of the mydriatic on the accommodation has passed off before ordering glasses. However, many experienced oculists prefer to "slightly under-correct the total refractive error," as you suggest.

## Proceedings of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-eighth Annual Meeting, held in Albany, on Tuesday, Wednesday, and Thursday, February 6, 7, and 8, 1894.

The President, Dr. HERMAN BENDELL, of Albany, in the Chair.

Hæmorrhagic Serous Effusion of the Pleura, with the Report of a Unique Case .- Dr. WILLIAM S. CHRESMAN, of Auburn, reported a case in which aspiration had been performed and repeated every ten days for six months, about a quart or three pints being removed at each operation. Anæmia had then begun to appear, and in January, 1892, he had irrigated the pleural cavity for two hours with Thiersch's solution, with the addition of a small quantity of iodine, in the hope of bringing the pleural surfaces into contact. Recovery had resulted. Then effusion had occurred on the other side, with dyspnœa. After seven or eight such aspirations, lavage had been repeated, as on the side first affected, with similar satisfactory results. He could find but one similar case-one that had been reported by Heineman. Subsequently, fluid had appeared in the abdominal cavity in the speaker's case, with anasarca. Zahn thought that such a condition was due to thrombosis of the azygous vein. Dr. W. S. Ely, of Rochester, had subsequently seen this case, and withdrawn a large quantity of fluid from the abdomen; he had performed aspiration thirteen times. In all, forty-nine operations had been performed upon this patient, and her general condition was now good. The speaker was unable to state the true pathology of the case. There was evidently a constitutional disorder of some kind.

Dr. W. E. Ford, of Utica, thought that the fibroid disease of the uterus with which the woman was suffering had had something to do with the case.

Researches on the Eliminating Power of Diseases, and the Relation between Vaccinia and Enteric Fever.—Dr. WILLIAM FINDER, of Troy, in a paper thus entitled, said he believed that typhoid fever occurring subsequently to smallpox had some influence in eliminating the poison of that disease. He believed that vaccinia and typhoid fever were closely related. He had vaccinated several persons in whom the vaccination had not taken; then they had suffered typhoid fever, and during the following year revaccination had been successful. He believed that in those cases the previous immunity had been removed by the fever.

Pneumonia of the Aged .- Dr. John H. Pryor, of Buffalo, emphasized the title pneumonia of the aged as distinguished from pneumonia in the aged. The disease was usually fatal, and often was without very marked phenomena. Many cases were obscure and elusive, and sometimes the condition was entirely overlooked. The value of the physical signs which ordinarily were considered was often lost in the cases under consideration, for they frequently ran an atypical course. He had observed that the disease occurred most commonly between November and May. The upper lobe was first affected, and the disease then extended downward. The left lung was oftener affected than the right, but both lungs were frequently involved. The patients sometimes died suddenly and without having had severe symptoms. Sometimes there were delirium and great prostration, with very high temperature, the temperature taken per rectum reaching 104° to 105° F. The respiration might not be very rapid, and the characteristic sputa were rarely present and were never purulent during the period of resolution. The countenance was anxious, the mind was perturbed, and after the crisis diarrhea frequently occurred. Often the first indications of the disease were found at the autopsy.

Dr. A. Jacobi, of New York, said that pneumonia of the aged often developed from bronchial catarrh, the same as in pneumonia in children. When there was a sudden rise of temperature from 100° to 103° he had usually observed that the issue was fatal.

The Diagnosis and Nomenclature of Fevers,-Dr. Nel-SON G. RICHMOND, of Fredonia, had observed that in western New York there was much confusion in the nomenclature of fevers, many fevers being confounded with typhoid. The reader thought tha a sny of those cases were not typhoid. The fever was gradual in ... onset and gradual in its subsidence, lasting from twenty-one to hirty-five days. The temperature increased gradually, seldom exceeding 103°; the tongue was sometimes clean and sometimes foul; in some cases there was constipation, in others there was not; there were also stupidity, indifference, jaundice, and emaciation. He had seen about fifty cases of this type, none of which had proved fatal. The name was really a matter of little consequence. There was seldom diarrhoa, sordes, brown tongue, delirium, or tenderness in the right iliac region. The South and West were the favorite habitats of malarial fever. The Lake Erie region was not now malarial. The question had occurred to the speaker, Was typhoid fever the only one prevalent in this region? As an answer, he was in favor of calling the condition under consideration Northern remittent fever. He was not sure whether the spleen in these cases was enlarged. No bacterial examinations had been made in any of them.

Dr. Jacobi thought it unfortunate that none of the author's patients had died, as the pathology was thus left obscure. He did not believe that a new name should be given until more of the pathology of the condition was known. Typhoid fever was often present, though many of the characteristic symptoms might be absent. If the spleen did not become smaller by the third week of the disease, the prognosis in cases of typhoid fever was apt to be bad. It was possible that many of the cases referred to by the reader of the paper were simply cases of fæcal poisoning in which constipation had continued for weeks without relief. In typhoid and malarial fever he believed that Ehrlich's test was a very reliable one.

Dr. Richmond stated that constipation was a very common disorder among the people in his section of the country. He had used calomel and other purgatives in his practice, as had been recommended by Dr. Jacobi. If he were to call such cases as he had described cases of typhoid fever, his opinion would not have been regarded as correct by those most concerned.

The Therapeutics of Oxygen.-Dr. A. W. CATLIN, of Brooklyn, read a paper in which he stated that the therapeutic use of oxygen was of very recent date. The treatment of disease by natural means was proving more and more efficacious as experience increased. Oxygen was a distinct remedial agentone that should not be left untried until the patient was in extremis. It was the surest and most satisfactory stimulant that we possessed, and was applicable to many conditions. In profound shock, from whatever cause, it had been found to exercise a reviving effect. It was taken up quickly by the blood, but its chief value was in its effect upon the nerve centers, upon which it exercised a quieting and soothing effect. In hæmorrhage from typhoid fever he bad seen relief in many cases. It would produce sleep, favor assimilation, and shorten the period of convalescence of typhoid fever. No agent was so well tolerated or so useful in restoring the equipoise of the physical condition. In cases of childbirth, pneumonia, bronchitis, and other exhausting diseases, the use of oxygen was indicated, and it should not be given late but early.

The Pathology of Diphtheria. - A general discussion on diphtheria, arranged by Dr. A. Walter Suiter, was opened with a paper by Dr. T. E. SATTERTHWAITE, of New York, who stated that the pathological anatomy of this disease was now well known. The pathogeny, which rested upon a bacterial basis, was not yet absolutely settled, though it was believed that the Klebs-Loeffler bacillus was the true cause. There was also, however, a diphtheroid disease, one that resembled diphtheria in many respects. The mere presence of a membrane did not necessarily indicate the existence of diphtheria. The bacilli of diphtheria might be present without the existence of a membrane. After the disease had fully developed all the organs of the body would show pathological changes. The diphtheritic membrane was usually attached to the underlying tissue. There was first local infection and then general extension of the disease. The peculiarities of the bacteria were described, and the difficulties of establishing the diagnosis. A diagnosis was usually to be confirmed by experiments upon animals. Bacteriologists found the bacilli in from seventeen to thirty-four per cent. of diphtheritic cases. With the bacilli of diphtheria there were also found streptococci and staphylococci.

Observations on the Diagnosis and on some Sanitary Aspects of Diphtheria .- Dr. A. WALTER SUITER, of Herkimer, stated that the identity of the Klebs-Loeffler bacillus was now definitely established. There was a diphtheria and a pseudodiphtheria. Many cases of so-called diphtheria were not true diphtheria. A clinical diagnosis in any given case was not usually sufficient. The general practitioner should in all cases have a laboratory assistant. The State should undertake the diagnosis in all cases of doubt. Laboratories should be established in various parts of the State, with suitable appliances and a sufficient appropriation therefor should be allowed. Oertel's discovery of a micrococcus had been followed by that of various others to the time of Klebs and Loeffler. Only by bacterial cultivations could positive results be obtained. About fifty per cent. of the cases which had formerly been treated as diphtheria had probably not been cases of diphtheria at all. Facts like this would tend to modify the statistics of the disease, as well as the diagnosis of any given case. Valuable results had been obtained in New York by the public examination of specimens which had been left for that purpose.

Croup and Diphtheria—their Unity or Duality.—Dr. W. H. Daly, of Pittsburgh, Pa., believed that differences in appearances in different cases of diphtheria were due to modifications which were not always readily explained. Arguments were possible for either unity or duality, and definite conclusions were not at present possible. The work with toxine inoculations had thrown much light on the history of the disease. Experimenters had produced in rabbits pareses, paralyses, and other phenomena similar to those which were seen in the human body. The practical application of their studies had shown that the use of laxatives resulted more favorably in the treatment of patients than the use of chloral and other nerve sedatives.

The speaker believed in the unity of the causes producing croup and diphtheria, but they might be modified in various ways by climate, hygiene, the conditions of the patient, etc. In the pharyngeal form of the disease the toxines and albumoses had their most favorable conditions for work, as they were readily absorbed. Hence constitutional affection quickly followed this form of the disease. Calomel was valuable in the treatment of the disease on account of its antiseptic effect. Not only diphtheria but many other zymotic diseases were to be explained by the influence of toxines, albumoses, and bacteria. The trouble was that the statements of experimenters were often too obscure for general comprehension. The speaker also made reference to the diphtheroid disease in which there was a mortality of five per cent. The disease was due to a bacillus, but perhaps there was no membrane.

The Comparative Status of Intubation of the Larynx.-Dr. JOSEPH O'DWYER, of New York, believed that deductions should be made upon this subject with great caution. A great variety of results had been obtained with intubation. The number of cases of recovery with those who had had a small experience did not prove anything; the same was true as to those whose cases had been few and the results fatal. Acute laryngeal stenosis was fatal in a certain class of young children in ninety per cent. of the cases. This statement showed the desperate character of the disease if nothing was done to relieve it, The experience of intubation with some operators had now reached hundreds of cases, and from their experience deductions of value as to the usefulness of the operation could now be made safely. In many of the series of cases there had been a large percentage of recoveries-as large as from twenty to forty per cent. Many operators had almost abandoned the use of tracheotomy. Secondary tracheotomy after intubation was seldom a success. The percentage of recoveries with most of the experienced operators in Europe was rather higher than with operators in this country. Recent experience was favorable to intubation.

Complicated Intubation of the Larynx.—Dr. William Halles, of Albany, narrated a case of diphtheria in a child which followed a severe attack of scarlatina. The case had also been complicated with albuminuria. Intubation had been performed; subsequently the condition of the child had become very serious, and salivation had been effected by means of the sublimation of calomel. The tube had been kept in position five days and then removed for an hour, when symptoms of suffocation had appeared and the tube had been replaced, with immediate relief. It had then been kept in position four days longer, and then definitively removed. The child had since suffered with an attack of chicken-pox and mumps, but was now quite well.

The Local Treatment of Diphtheria.—Dr. A. Jacobi, of New York, believed that the local treatment of diphtheria was best studied on external wounds or on diphtheria of the vagina, One should not use powders in the treatment of laryngeal diph-

theria, as they were apt to produce nausea. Bad-tasting and nauseating medicines of all kinds should also be avoided. It should be remembered that gargles were effective only as far down as the pillars of the soft palate; therefore most of the gargling was useless. The dangers in diphtheria were, first, from suffocation; second, from heart failure and exhaustion; and, third, from sepsis. Sepsis and a fatal termination usually occurred in cases in which the nares were affected. The diphtheritic membrane should be destroyed by local applications of a mixture of equal parts of carbolic acid and glycerin, which was more effective than 'chlorine water. In general, local applications would be allowed by adults and large children. Smaller children would struggle and become exhausted if applications were attempted. The struggling was a serious matter with small and very sick children; besides, it was possible in such cases, as a rule, only to reach the tonsils with the application, and sepsis did not usually take place through this avenue. It was better with small children to give internally medicines which were easily absorbed, including iron, mercury, chlorine, and iodine. The form of diphtheria which was most dangerous was that which attacked the nares and the nasopharynx. In some cases the diphtheritic membrane was tough, in others soft and easily macerated. In the latter cases the virus was most readily absorbed. Where it was possible, it was well to apply medicines to the throat with cotton wrapped upon a long probang, and they should be applied as thoroughly as possible to the entire membranous surface. If the nares were affected, the medicine might be poured into the nose with a feeding cup, or a small syringe might be used. The use of an irrigator for the nose was not without danger. Applications should be made with the patient in a recumbent or semi-recumbent posture. Mild applications, including salt water and limewater, would also be found useful in many cases for their cleansing effects, also carbolic acid, creolin, and weak solutions of bichloride of mercury. Papayotin, in a five-per-cent. solution, or trypsin of similar strength, combined with bicarbonate of sodium, was also useful. For the treatment of adenitis associated with diphtheria, preventive and curative measures should be used. Ice would be effective in some cases. Iodoform, if given by injection, was too painful. If the swelling was extensive, long and deep incisions should be made, and they should be made as early as possible in the history of the disease. In cases in which hæmorrhages occurred, suitable astringents should be used, but solutions of iron should never be used to check hæmorrhage. The paralyses of diphtheria should be treated by means of friction. The most urgent cases were those in which the muscles of respiration were involved. If electricity was used, one must be careful that the muscles were not overstimulated.

The General Treatment of Diphtheria. - Dr. E. F. Brush, of Mount Vernon, believed that the object of treatment should be to support the strength of the patient until the dangerous period of the disease was past. He did not believe in any specific treatment. The disease was not due to a single cause. Danger was to be apprehended from the use of the potent drugs which were so highly recommended. Death in some cases of the disease was inevitable, whatever treatment might be adopted. The general indications of each epidemic should be studied. The intestinal tract should be kept open; calomel and suitable enemata should be given, especially when the temperature was above 103°. Tincture of chloride of iron with potassium was the best medicine which had yet been found for the treatment of the disease. Fluid food should be given, especially buttermilk, whey, oatmeal water, soups, and broths. Alcohol was quickly absorbed and eliminated, and large quantities of it would be tolerated. Turpentine might be given if for any reason alcohol was objected to; if necessary, alcohol might be given through a stomach-tube.

The Use of Tartar Emetic in Diphtheria. — Dr. H. DE V. PRATT, of Elmira, believed that any method of treatment should be subject to modification and change. Diphtheria presented different forms in different epidemics; consequently the treatment must vary from time to time. In the last five years the speaker had treated forty-seven cases with tartar emetic and opium, and only two of the patients had died. He was accustomed to give a thirtieth of a grain of tartar emetic, with a sufficient quantity of opium, to very young children every hour for twenty-four hours. On the following day the dose was doubled, and this treatment was continued as long as the conditions indicated it. The constitutional effects of the tartar emetic were noticeable within a few hours, but toleration was quickly established, and in his experience no contraindications had been seen. It hastened the progress of the disease and then checked the development of the membrane, no matter where the latter was developed. The constitutional symptoms would improve with the change of the local conditions. The nourishment of the patient was also to be considered, the discharges were to be disinfected, and strict cleanliness was to be insisted upon. There had been no serious sequelæ in any of his cases; hence he must conclude that the treatment had been efficient. It was not an emetic treatment; there was no depression after the first few hours; the drug acted directly upon the poison of the disease.

(To be continued.)

#### SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

Meeting of December 6, 1893.

The President, Dr. FREDERICK H. WIGGIN, in the Chair.

Bilateral Ovarian Fibro-sarcoma.—The President presented a specimen and read the history of the case. (See page 172.)

Intra-abdominal Sarcoma.—Dr. Charles Phelps presented a specimen and related the history of the case. (See page 172.)

Dr. Joseph D. Bryant said that he had taken a good deal of interest in this case because he had seen it prior to the operation, and had expressed the opinion that the tumor was attached to the abdominal wall, although he was not certain whether or not it had had an intra-abdominal development or had originated in the abdominal wall. The ultimate conclusion as to its attachment to the abdominal wall had been reached after examination by placing the patient on her hands and knees. He was not aware if the reader had mentioned the fact whether the peritonæum had covered the posterior surface of the tumor or not. He thought Dr. Phelps's conclusion that it had originated intraperitoneally was feasible.

Dr. J. W. S. Gouley said he had been at first very much in doubt as to the exact site of the tumor, and he had ventured to express the provisional opinion that it had originated in the mesentery or omentum, but the operation had shown that it had a very different origin. The tumor, lying underneath the great abdominal aponeurosis, seemed to have extended itself in the direction of least resistance—i. e., backward into the peritoneal cavity—so that the growth was both intraperitoneal and extraperitoneal. He had had from the very first no doubt that it was a hard sarcoma. The explanation given by Dr. Phelps was an ingenious one, yet it did not seem to be in accordance with the findings of the pathologist. He had been particularly interested in the operation because of the amount of perito-

næum removed; apparently a portion of peritonæum five by six inches had been taken away, and yet there had been no difficulty in approximating the edges of the wound. Hence we should not be discouraged in removing tumors of the abdominal parietes if the tissues of the abdominal wall were sufficiently redundant. There had been rapid union of the peritoneal surfaces in this case.

Dr. Phelps said that microscopical examination so far had been confined to the extra-mesenteric portion of the tumor, and consequently did not affect the question of its glandular origin. The opinion he had expressed, however, was purely speculative, and he was content to leave it as such.

Sacculated Aneurysm of the Abdominal Aorta cured Spontaneously .- Dr. PARKER SYMS presented the specimen and said that the patient had been a man of about forty years of age who had been admitted to the colored hospital in 1892. Until nine months before admission the man had been well. When admitted he was emaciated and suffered from abdominal pain after eating, and had marked indigestion. The attending physician had found a large pulsating tumor at the upper part of the abdomen and had made a diagnosis of aneurysm. The patient had been referred to Dr. Syms for surgical treatment some weeks after admission. Then there had been no pulsation and Dr. Syms had thought it probably a tumor of the pancreas. Exploratory laparotomy had been done for the purpose of diag nosis and possible treatment. This tumor had been found firmly imbedded in a mass of adhesions, extending down to and attached to the pancreas.

Unfortunately, the man had died of shock. The specimen was presented as being of interest in connection with the paper of the evening.

Pyelitis, Cystitis, Hæmaturia; Cystotomy, Nephrectomy, Cure.—The patient was presented by Dr. Syms, who gave the following history of the case:

James R., aged twenty-two years, had first been seen by him three years ago. Since the age of twelve years he had had bladder trouble, causing pain and very frequent micturition. When first seen by the speaker he had passed his urine every few minutes, wetting his bed at night, and had been absolutely unable to work on account of this trouble. He had been treated at a "quack" hospital in Buffalo, where they had told him he had a stricture. They told him they had operated on the stricture and they had passed sounds on him until his money was exhausted, when they had discharged him "cured!" in the condition in which Dr. Syms had found him. His urine had been ammoniacal, had been loaded with pus and mucus, and had contained constantly a small amount of blood as shown by the microscope. He had well-marked cystitis; and the speaker had suspected stone. Sounding for stone had given a negative result. He had never had gonorrhea, and had no stricture.

To more thoroughly explore and to drain his bladder a perineal cystotomy was done. No stone was found, and no bladder tumor. The drainage and attendant treatment had cured the cystitis in a few weeks, and he had been able to hold his urine for about an hour during the day, and at night had had to urinate but two or three times. His urine had become fairly clear, but had continued to contain a small amount of pus and blood. The right kidney had been quite tender and a renal calculus or pyelitis had been suspected from some other cause. Therefore two years ago an exploratory nephrotomy had been done. The kidney had been found to be of normal size. A small, hard mass could be felt in the pelvis; to an exploring needle this had given a grating sensation. The pelvis had been incised and this mass had been found to be a spot of cicatricial tissue. At the first operation the patient had bled

unusually; at this operation be had had so much homorrhage as to indicate that he was a "bleeder." The speaker had curetted the diseased spot and had meant to drain the kidney through the wound; but, as no amount of packing would stop the bleeding from the kidney, the organ had been rapidly removed and the wound packed and sutured. The patient had made an uneventful recovery, except for the interesting fact that scarlet fever had occurred about ten days after the operation. His one kidney had carried him safely through the disease, excreting some days as much as seventy ounces of urine. The patient was now well, could retain his urine, and was earning his living. His urine was normal, free from blood and pus. Dr. Syns thought that this patient's trouble was entirely due to the use of dirty instruments, infecting the bladder, and thus the kidney.

Dr. J. M. Byron said that this kind of cystitis was not very uncommon. He had seen several cases in which manipulation of the bladder had produced a gangrenous cystitis. Two or three weeks ago a case had been presented to the New York Pathological Society in which the cause of the cystitis had been traced to the introduction of improperly sterilized instruments. Some years ago a Russian observer had described a particular kind of bacterium which he had considered the special cause of this form of cystitis, but subsequent observations by other experimenters had shown these pathological changes to be generally due to the Bacillus coli commune, which, under certain circumstances, became exceedingly virulent. The occurrence of hæmaturia and the persistent cystitis showed that the process must have involved more than the nucous membrane.

Internal Aneurysm in European Residents of Japan.

Dr. S. Eldridge read a paper on this subject. (See page 165.) Dr. A. A. SMITH said that the paper seemed to clearly bring out the fact that aneurysm was much more prevalent in Japan than in any other country with which he was familiar, and it seemed also to confirm the view, held by the vast majority of observers, that syphilis was responsible for the large proportion of aneurysms occurring in any country. He was disappointed that no satisfactory explanation was offered for the large proportion of aneurysms in Japan aside from syphilis as a cause. He had been greatly interested in what had been said about the possible bearing of filarial infection on the occurrence of aneurysm. While syphilis had an important bearing on the ætiology of aneurysm, it was not uncommon, he thought, to see cases apparently having a different causation. No doubt luxurious living and particularly alcoholism had much to do with the changes in the walls of the arterial system which gave rise to aneurysm. All the various causes leading to increased arterial tension would seem to be to a certain extent factors in its production. He had felt that perhaps gout played a more important part than was ordinarily attributed to it, and he had sometimes thought that even the rheumatic tendency had something to do with the development of the changes in the arterial walls, yet he was forced to admit that in many cases he had been puzzled to find any satisfactory explanation for the aneurysm. He was surprised to hear of the rapid progress of many of the cases of aneurysm coming under the author's observation; perhaps climatic influence might be largely responsible for this. He would, however, be exceedingly doubtful about this having any special effect in causing those changes in the arteries which led to aneurysm. He would like to ask whether the European residents were people who had acquired gout, and also whether kidney disease was prevalent, and particularly whether the cirrhotic kidney was common, for aneurysm seemed to be often associated with this form of renal disease.

Dr. R. C. M. Page said that we might consider two classes of ætiological factors: (1) Anything which increased the blood

pressure; and (2) anything which weakened the walls of the arteries.

In the first class were to be included proximity to the heart and the direction of the vessel, whether straight or curved. Where the vessel was curved it received a greater impulse, directed especially against the periphery. In eight hundred and eighty cases of aneurysm collected by Sibson, six hundred and thirty-two had occurred in the arch of the aorta alone, seventy-one in the thoracic aorta, and a hundred and seventyseven in the abdominal aorta. It was easy to understand why the majority of these aneurysms should occur in the arch and so few in the thoracic aorta; but in the abdominal aorta the frequency was probably due to the facts that the vessel in that region was more subject to direct violence and injury, especially among laboring people, and also because the arterial coats, being bent upon themselves in almost every movement of the body, became brittle. As the European residents were not subjected to violence, he thought this accounted for the comparative rarity of abdominal aneurysm among them. Anything which gave rise to hypertrophy of the heart, notably aortic regurgitation by causing enormous enlargement of the left ventricle, resulted in the blood being driven with great violence into the arch of the aorta, and therefore it was not at all uncommon to find aneurysm of the arch associated with aortic regurgitation. Owing to hypertrophy of the left ventricle, we might also find aneurysm in connection with interstitial nephritis and in alcoholic subjects, as the habitual use of cardiac stimulants caused an increase in the force of the blood current. Any disease which would give rise to endarteritis with subsequent atheroma of course caused weakening of the blood-vessels, and of all these causes syphilis was the most important, and next to this, he would say, gout. Lead poisoning was stated by some to be a cause, but, as it was not infrequently associated with gout, it might be placed under the same head. Indeed, Garrod had stated that one third of all his hospital cases of gout could be traced to lead poisoning. The speaker thought rheumatism had something to do in producing endarteritis. It was not necessary to have an endarteritis, and therefore not necessary to have syphilis, to produce aneurysm. He had treated within the past six weeks a case in which there had been nothing present which would cause endarteritis, yet there had been a small aneurysm of the arch of the aorta which had developed as a result of occupation, the patient being required to do much lifting of heavy weights. The text-books gave a long list of diseases which might be mistaken for aneurysm, but it was not easy to mistake aneurysm of the arch of the arra. He recalled one case of mitral stenosis which had simulated aortic aneurysm, but the presence of the obstructive murmur had led him to believe that it was an enlargement of the left auricle and not an aneurysm, and this had subsequently proved to be the case. To diagnosticate abdominal aneurysm from other pulsating tumors, the patient should be placed in the knee-chest position. The diagnosis of aneurysm of the thoracic norta was much more difficult. Some twenty-five years ago there bad been such a case, and it had so closely simulated pleurisy with effusion that it had been exhibited at the clinic at Bellevue Hospital as a typical case of that condition, yet the post mortem examination had shown it to be an aneurysm of the thoracic aorta. There was no doubt that in a certain number of cases the Tufnell method was very beneficial. It consisted in placing the patient in the recumbent posture and giving the maximum of nutrition while the force of the heart was kept at the minimum. This, along with the administration of iodide of potassium, caused a number of patients to get well. These cases were those in which there had not been much destruction of the inner and middle coats of the artery, or at least in which there bad

been no atheromatous changes. The speaker recalled the fact that several years ago a physician from the South, who had apparently got well under this treatment, had suddenly died without a previous reappearance of the tumor. His death had been due to rupture of the artery at this point before the tumor had had a chance to appear. Iodide of potassium was the ideal remedy, but in some cases even small doses—e. g., five grains—caused intense salivation. In one such case he had changed to the chloride of barium. He thought the addition of arsenic was an advantage.

Dr. E. LE FEVRE exhibited a specimen showing the effect of the filaria on the blood-vessels and heart of a dog. This was the first case of this kind he had seen. The dog was three years old, was born in Newark, and had never been taken out of the State. A few months ago, while in apparent health, he had suddenly fallen dead, and examination had shown rupture of the heart, due to immense quantities of filariæ in both sides of the heart, and extending into the vessels.

Dr. Byron said that we had recently come to know of a number of diseases which were undoubtedly produced by parasites which originally lived in the lower animals, and by some means or other had been communicated to man. Some years ago he had presented to this society a case of actinomycosis, which was a new disease so far as our knowledge of it was concerned. We knew also of the existence of filariasis in the lower animals. In Sicily filariæ had been noticed among sheep recently introduced into the country, yet so far they had been extremely rare among the inhabitants. It was generally understood that the prominent symptom of filariasis was hæmaturia; yet along the shores of the Amazon and of the Nile it produced abscess of the liver and a serocele, or so-called hydrocele. He knew of only one case of the Distoma hepaticum; yet this parasite was constantly found in animals, and might be communicated to human beings, for instance, by eating the liver of sheep infected with these parasites. As the filaria produced aneurysm of the aorta in the dog, why should it not produce the same condition in man?

Dr. Albert L. Gihon, of the navy, being called upon by the president, said that he had had a few years' experience in Japan, and could confirm Dr. Eldridge's statement that syphilis was an inducing cause of aortic aneurysm in that country; indeed, it seemed to him that it was at the bottom of all the other diseases he had encountered there, which fact made the practice of medicine comparatively simple. The Japanese themselves were not slow to learn that mercury and iodide of potassium were potent remedies in the treatment, and, with their accustomed haste and lack of thoroughness, went to work and very generally salivated their fellow-countrymen. They used to get their iodide from a house in Shanghai, but, objecting to its price and suggestively inquiring whether a cheaper article could not be had, were obligingly supplied with one especially sophisticated to their outlay.

He thought that the establishment by his friend Dr. Newton, of the British Navy, of a system of regulations and inspection of prostitutes in Japan (the erection of a Temple to Mercury at the approach to the Temple of Venus, as it was termed at the time) had had much to do with the eradication of venereal disease among the residents and patrons of the Yoshiwaras. He had himself, at the request of the local authorities of Nagasaki, where he had been stationed in charge of the hospitalship Idaho, proposed to organize a lock hospital for the pretection of that community, but the commanding officer of the station had been unwilling to authorize such action.

With regard to the treatment of aortic aneurysm by rest and iodide of potassium, to which some of the speakers had referred, Dr. Gihon mentioned the case of his friend Dr. Thomas

F. Wood, secretary of the State Board of Health of North Carolina, who, having discovered himself to be a victim of this disease, had deliberately gone to bed and had remained there thirteen months, taking large doses of potassium iodide, and at the end of this time had got up, without his aneurysus, a strong, hearty man, and had died years after of another affection.

While in charge of the United States Naval Hospital at Brooklyn he had had three similar cases—one in a marine, who, after the ordeal contemplated had been explained to him, had gone to bed and had remained there eleven months. Near the end of his confinement, while lying awake one night, he had espied a thief enter the ward and carry off the men's clothing, and had jumped out of bed and secured him without injury to himself. Soon after this he had been declared cured of his aneurysm and had subsequently died of pneumonia, and at the necropsy no aneurysm had been found, as his friend, Medical Director Bogert, of this society, who had succeeded him in charge of that hospital, could bear witness.

Dr. Edward S. Bogert, of the navy, briefly confirmed Dr. Gihon's statement.

Dr. Gouley said that the author had referred to many different factors concerned in the production of ancurysm, beginning with syphilis. He would like to ask whether each and every factor was not really a remote cause, giving rise to disturbance in metabolism and to hyperlithemia, which was known to excite degenerative changes in the arteries, that in consequence were weakened and liable to expansion b, the blood pressure. The syphilitic subject was depressed, and his system in no fit condition for proper metabolism. The same might be said of the drunkard, the glutton, the gouty, and the rheumatic. All these persons were hyperlithemic and liable to suffer from degenerative changes in their arteries, large and small, and consequently from ancurysms.

Regarding the question of parasitic invasion, he said that he had noted that only animal parasites had been mentioned. All the physicians and surgeons present knew that occasionally patients were brought to the hospitals who died very suddenly and mysteriously within a few hours after admission, and the autopsy revealed what was known as ulcerative endocarditis. What was this but a microbic invasion? Might not an invasion of some other species of microbia lead to the formation of colonies of greater or lesser size in the arteries, and thus so weaken the coats of the arteries as to allow of their excessive expansion under the blood pressure? He would like to ask the reader of the paper whether in Japan he had seen aneurysms which were apparent on the surface of the body, such as on the head, neck, or extremities.

The speaker recalled the case of a medical man who had presented very unequivocal signs of aneurysm of the abdominal aorta. The patient had not known the nature of the tumor until the speaker had informed him of it, and also of the probability of its bursting soon. He had been placed in bed, and treated according to the method of Dr. Tufnell. After a time the tumor had hardened, and the man had lived six or eight months, and finally died of fibroid phthisis. He could not see what good could possibly come from the administration of iodide of potassium in cases of aneurysm. If, as Dr. Page had said, it got rid of the fibrous tissue formed around the aneurysm by Nature to protect it, it was wrong to attempt to remove this, and its administration should cause a decided increase in the size of the aneurysm. He failed to see the good done by iodide of potassium in syphilis, and every year he gave less of it, relying more and more on mercury. He had known iodide of potassium do a great deal of harm; he had never known it do much good.

Dr. PARKER SYMS said that he had been taught to believe

that syphilis was the chief cause of aneurysm, and he still held that opinion, though his experience had not borne it out, for several of his cases of peripheral aneurysm had given no history of syphilis and had shown no manifestations of it. Of course this was but negative evidence. He held that anything which weakened the arterial wall was a predisposing cause of aneurysm, hence any cause of endarteritis was a factor. Then anything causing an increase in the blood pressure might become the exciting cause. In some of his cases traumatism had very distinctly been an element in the production of the aneurysm. He was very much surprised that so few peripheral aneurysms were found in Japan in proportion to those of the thoracic and abdominal norta.

Dr. Matthew D. Field said that he had been especially interested in the remarks that had been made about sypbilis in Japan. Dr. Sachs had recently said in a discussion at the Neurological Society that the latest and most accurate statistics gave syphilis as the cause of over ninety-two per cent. of all cases of locomotor ataxia, and that over sixty per cent. of cases of paresis were due to syphilis. The general opinion was, however, that syphilis was the predisposing cause, and that there was some other factor. The same might be said of the author's experience in Japan. If this were not so, how was the experience of Dr. Post to be explained, for he had found syphilis very prevalent in Syria, yet there was practically no aneurysm there. Hence, as in nervous diseases, it was syphilis plus something else, and he was very glad that the author had made a suggestion as to what the something else might be.

Dr. ELDRIDGE said, with reference to gout and rheumatism, that, while gout might be present in a masked form, it was very rare to find it frankly manifested. The same was true with regard to articular rheumatism, which was of infrequent occurrence, and, perhaps for that reason, valvular disease of the heart was also rare. The brief duration of the aneurysms was certainly a remarkable feature; to the best of his recollection, the average period was certainly not more than one or two years, and often very much less. Nephritis was not at all common, and the cirrhotic form was not more frequent than the other varieties. He did not think the statistics of Simpson would hold in Japan, and the whole question was a very puzzling one to him. The point made by Dr. Page on regurgitation in the development of aneurysm of the arch he had answered in connection with his consideration of valvular disease in general. Tufnell's treatment he had tried in a number of cases, but had had a partial success in one only, and that had been a case of aneurysm of the abdominal aorts, which, although previously well marked, had almost entirely disappeared under this treatment. The patient then, taking advantage of a difference of opinion between his medical advisers, had gone to work, and had died suddenly. The postmortem examination had shown that the walls of the sac were thickened and consolidated, and that the relapse had taken place at a thin point where a secondary sacculation had formed. While he thought syphilis was the chief cause of aneurysm in Japan, he could not of course help believing that other causes had a share in its production; still, such an enormous proportion of the cases coming under his observation had such a clear syphilitic history that had it not been known that syphilis was a predisposing cause it would have still directed his attention to this disease as an ætiological factor. In his whole experience he had seen only one peripheral aneurysm in a European in Japan, and miliary aneurysms seemed to be almost equally rare. Probably because the aneurysms were of such short duration, calcareous infiltration was very infrequent. He could not explain the action of iodide of potassium, but it certainly relieved the intense pain and some of the urgent symptoms,

and, in his experience, had always been of some benefit. A pretty large experience in the treatment of syphilis in general had led him to use this drug less and less, and he now treated many cases entirely without it, though, where really called for, he had, of course, found it invaluable.

He believed with Dr. Field that these aneurysms were due to syphilis plus an unknown factor; he was sorry that this other factor had not as yet been definitely determined. It was frequently difficult to say what patient had a syphilitic history, and often the only evidence was to be found in the lesion for which the patient sought treatment. In this way aneurysm might be the only evidence of syphilis.

On motion of Dr. W. R. Townsend, the society tendered a vote of thanks to Dr. Eldridge for his very able and valuable paper.

# Book Notices.

Atlas of Head Sections. Fifty-three Engraved Copperplates of Frozen Sections of the Head, and Fifty-three Key Plates with Descriptive Texts. By WILLIAM MACEWEN, M. D. New York: Macmillan & Co., 1893. Pp. ix- . [Price, \$21.]

The author states, in the introduction to this beautiful collection of plates, that the fifty-three sections represented in this volume were selected from over a hundred specimens. By making a section of the head it has been possible for the artist to delineate the relation of the brain to the exterior of the skull, thus making these plates of great value to the student of cephalic topography.

While each plate is complete in itself, various structures may be traced through a series of sections, coronal, sagittal, and horizontal. Coronal and horizontal sections of the head of a child are represented as well as those of an adult. The main points in each plate are described in a key representing the plate in outline.

This work can only be compared with Dalton's magnificent topographical atlas of the brain, now out of print, or Frazer's more recent atlas. The plates are well executed, and the volume is a necessity to every surgeon likely to be called upon to operate on the brain in cases of disease.

Outlines of Obstetrics. A Syllabus of Lectures delivered at the Long Island College Hospital. By Charles Jewett, A. M., M. D., Professor of Obstetrics and Pædiatrics in the College and Obstetrician to the Hospital. Edited by Harold F. Jewett, M. D. Philadelphia: W. B. Saunders, 1894. Pp. 264

The author states that this little volume is intended as an aid to the study of obstetrics in both the didactic and the practical work of the college course. Its arrangement enables the student to secure a classified knowledge of the outlines of this subject.

The work includes a syllabus of the anatomy of the female genital organs, of the physiology and pathology of pregnancy, of the physiology of labor and of the puerperal state, of obstetric surgery, and of the pathology of labor and of the puerperium.

The author's style is terse and vigorous, and we believe that the volume will prove very useful for the purposes intended.

The Anatomy and Surgical Treatment of Hernia. By Henry O. Marcy, A. M., M. D., LL. D., of Boston, President of the American Medical Association; Surgeon to the Hospital for 153

Women, Cambridge, etc. With Sixty-six Full-page Heliotype and Lithographic Plates, including Eight Colored Plates from Bourgery, and Thirty-seven Illustrations in the Text. New York: D. Appleton & Company, 1892. Pp. viii-421. [Price, §15.]

The publishers of this work have certainly conferred a favor on the profession by the liberality they have displayed in the numerous magnificent illustrations that the author has so carefully selected from the rare and comparatively inaccessible volumes of Sir Astley Cooper, Bourgery, Darrach, Guthrie, Scarpa, and Cloquet.

After a general consideration of the frequency of hernia, the anatomy of the parts involved in inguinal hernia is described. The author then describes the anatomy of congenital hernia, including encysted hernia. The symptoms and complications of direct and of irreducible inguinal hernia are described, with numerous excerpta from the older writers; in this we think that Dr. Marcy has not done bimself justice, because his own experience is sufficiently extensive to warrant him in indulging in personal narration rather than quotation.

The author advises early recourse to an aseptic operation for the relief of strangulated inguinal hernia, and it is his custom to sew the divided sac across its neck with a double tendon suture and then excise the proximal portion of the sac.

The anatomy of femoral hernia and the operative measures for its relief, when strangulated, are next described. The author's operative procedure for the relief of this condition is similar to that for inguinal hernia.

Short chapters are devoted to obturator heroia, ischiadic hernia, cæcal hernia, ovarian hernia, cystic hernia, ventral hernia, and diaphragmatic hernia.

In the chapter on umbilical hernia there are slight misprints on page 198, Æginatus being written for Ægineta, and Desault being spelt with two s's; and on page 204 Lucas-Championnière is referred to as Championnière. On page 109 and elsewhere Hagedorn is spelled Hagerdorn.

An interesting review of the operative measures advocated for the cure of hernia is given, also a review of the animal suture. Nowhere can a more complete history of this latter surgical resource be found.

The latter chapters of the volume are devoted to the treatment of hernia, especially by the use of the buried tendon suture with which the author's name has been so long connected. It would be futile to here review the details of an operation that has produced in his hands such satisfactory results.

Dr. Marcy does not aim to do more than make this a practical treatise on hernia as met with in general practice, and the illustrations so elucidate the text that the volume will serve as a guide to those who are not frequently called upon to perform this operation and whose recollection of anatomical relations is somewhat rusty.

The beautiful typography and general execution of the work make it an édition de luxe.

Climates of the United States, in Colors. Popular Edition of Denison's Charts, with Additions. By Charles Denison, A. M., M. D., Denver, Col., Professor of the Diseases of the Chest and of Climatology, Medical College, University of Denver, etc. Designed for the use of Physicians, Tourists, Health Seekers, Farmers, and Schools. Chicago: The W. T. Keener Company, 1893. Pp. 47. [Price, \$1.]

This popular edition of the author's excellent charts gives the annual cloudiness, annual rainfall and temperature, and annual wind charts, also seasonal charts showing combined atmospheric humidities for spring, summer, autumn, and winter, as well as the isotherms and wind indications for each of these seasons. In all, there are twelve charts and eleven tables that are the result of an immense amount of labor in condensing the facts stated in the annual reports of the chief signal officer of the army for eleven years.

This volume should find a large sale, appealing, as it does, to the interests of so many occupations.

A Manual of Practical Hygiene, designed for Sanitary and Health Officers, Practitioners, and Students of Medicine. By W. M. L. Coplin, M. D., Adjunct Professor of Hygiene, Demonstrator of Pathology, and Curator of the Museum, Jefferson Medical College, etc., and D. Bevan, M. D., Instructor in Hygiene and Clinical Microscopy, Jefferson Medical College, etc. With an Introduction by H. A. Hare, M. D., Professor of Therapeutics, Materia Medica, and Hygiene in Jefferson Medical College, Philadelphia. With One Hendred and Forty Illustrations, many of which are printed in Colors. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xvi-25 to 456. [Price, \$4.]

The first chapter in this volume is devoted to the cause and prevention of disease, and in it the authors state that it is not of sufficient importance to cavil over the distinction between the terms contagion and infection in referring to communicable diseases. Throughout the volume the terms are used synonymously, an unfortunate fact for the student.

While the authors state that there have been no well-founded objections to isolation and segregation of patients afflicted with leprosy, syphilis, or tuberculosis, yet it seems to us that there are excellent objections-leprosy, to be communicable, requires certain factors of environment and idiosyncrasy, and one of the best boards of health in this country, that of Louisiana, refused some years ago to be a party to a proposition that would make life more unendurable for the leper by isolating him from friends and relatives. Fournier is authority for a statement that corroborates the experience of all practitioners of extended experience, that most cases of syphilis are (to use bis expression) legitimately acquired; and the caveat emptor of the market-place may be used by the sanitarian when he is asked to be a party to enact laws that are repugnant, that are partisan in their application to one delinquent only (lock-hospitals for males have always failed to accomplish their intended purpose), and that are not justified by any prevalence of syphilis; while the great prevalence of tuberculosis has convinced the profession that the most careful supervision of food stuffs and the greatest sanitary care of the tuberculous would but in a measure limit that disease as long as it was possible for a person to be affected with it for years and present no decided physical symptoms.

The duration of isolation for each of the communicable diseases is specified, and disinfection is described with sufficient detail.

The second chapter deals with individual hygiene during infancy, childhood, and puberty.

The third chapter considers the sanitary features of clothing.

The chapter on food describes the latest methods of testing
milk. The Beimling process is accurately explained, and a sufficiently detailed account of meat inspection is given.

The chapters on water and air, while not exhaustive, are still sufficiently complete to answer the requirements of the practitioner or student.

The chapter on climate is properly written with reference to the needs of the American physician.

The chapter on soil, like the chapters on water and air,

does not aim to be compendious, but simply gives such facts as may be of daily use.

One of the most concise as well as interesting chapters in the volume is that on habitations. It describes the various sanitary features of a house and the method of making a sanitary inspection thereof.

The chapter on sewage is somewhat too concise.

The authors have evidently aimed to make their work compact rather than comprehensive; and, while this has caused the omission of certain topics that are familiar in works on hygiene, the reader will appreciate their avoidance of voluminousness.

What the book does give is, on the whole, a practical summary of recent progress in hygiene.

The Technique of Post-mortem Examination. By Ludvig Herroen, M. D., Pathologist to the Cook County Hospital, Chicago, etc. With Forty-one Illustrations. Chicago: The W. T. Keener Company, 1894. Pp. viii-172. [Price, \$1.75.]

The author states that, while this little book has been prepared for the guidance of medical students, still its scope and method have been arranged with the intention of making it useful to the practitioner.

The form of record and the instruments employed, as well as the various steps in the examination of the body, are described, and the text is elucidated by forty-one illustrations, but we note that Figure 24 is a repetition of Figure 5.

We are glad to see that the author urges that the necropsy should be made as soon as practicable after death.

The work is admirably arranged and printed, and it is the best manual on this subject that we have seen.

A Theory of Development and Heredity. By Henry B. Orr, Ph. D., Professor at the Tulane University of Louisiana. New York and London: Macmillan & Co., 1893. Pp. ix-255. [Price, \$1.50.]

The author considers that an explanation of growth, development, and inheritance is afforded by the assumption of the creation of a primitive mass of protoplasm that acquires nervous co-ordinations which influence activity and growth. As this mass divides and subdivides it adds continually new co-ordinations to those already acquired; the process of growth and development comes by repetition to have the character of reflex action—that is, becomes more rapid. "As the same forces act on each generation and form a series of stimuli that are similar for each generation, so each generation repeats in its life the course of development followed by all its ancestors."

We do not believe there is any evidence that will sustain the author's conclusion that the greatest part of the molecular change which is brought about in living matter by the action of external forces is that change which occurs in the nervous organization. In the first place, he confounds the simulation of the functions of the nervous system with the existence of nervous structures. It does not seem to us that the latter need be assumed to explain the phenomena of development and heredity in plants and the lower animals. A study of the phagocytic activity of white blood-cells suffices to explain all such phenomena by analogy. And yet there is no change in the nervous organization of the phagocyte, and there is no nervous organization to be changed. Such a position ignores the inherent forces of a living cell, and the nervous system in living organisms is but an incident, a medium for the transmission of afferent and efferent impulses in the lower forms, and, in addition to these, in the higher forms for storing impressions.

The study of micro-organisms has shown that while, mor-

phologically, there is no change, yet by changes in environment a harmful may in successive generations develop into a harmless microbe. Such a change is necessarily consequent upon some intrinsic transformation of the micro-organism that is certainly independent of any nervous organization. Reasoning by his method of analogy, subject to fallacy as such a method of logic has always been considered, we are justified in concluding that in higher forms of living matter molecular change is produced by the action of external forces independent of even the most elementary form of nervous structure.

Neither heredity nor atavism satisfactorily explains all the phenomena of life; and environment, including education and training, necessarily influences beneficially or disadvantageously the vital phenomena.

We do not believe the evolutionary theory suffices to explain either development or heredity, for there are gulfs in the continuity of the surface of such speculation that are, and probably will remain, impassable.

The Report of the Department of Pathology of the University College, London, 1892-'93. Together with a Collection of Papers and Abstracts published from the Laboratory. Volume I. Edited by Victor Horsley, F. R. S., F. R. C. S., and RUBERT BOYCE, M. B.

This volume is composed of a collection of publications by investigators at work in the pathological laboratory of the University College. The papers embraced in it have been published during the period from the beginning of 1892 to May, 1893, and have appeared in various medical and scientific journals. Actually the volume is a collection of reprints on pathology and histology, and it is a most creditable exposition of the character of the work done in the institution.

Relation d'une épidémie de choléra. (Étude clinique et expérimentale.) Par MM. A. MAIRET, professeur de clinique des maladies mentales et nerveuses, et F. J. Bosc, chef de clinique des maladies mentales et nerveuses à la Faculté de médecine de Montpellier. Avec 4 planches et 11 tracés dans le texte. Montpellier: Charles Boehm, 1893. Pp. 6-98.

This volume gives the observations made by the authors during an epidemic of cholera at the Montpellier Insane Asylum in June and July of 1893. The disease was introduced into the institution by a male nurse from Marseilles, and there were fifty-five cases of cholera in all—twenty-three in males and thirty-two in females.

The authors trace the origin and the course of the epidemic very carefully, and consider that, as the disease did not appear in the wards for females until sixteen days after it had existed in those for males, the water supply of the institution could not be considered as the disseminating medium.

The nurse first affected had charge of the linen, and was on duty two days after he became sick, so the authors think it is probable that the clothing was infected by him during those days. Their experience showed that the number of cases increased when the temperature and the height of the barometer were elevated.

The symptomatology, pathology, diagnosis, prophylaxis, and treatment are very fully considered.

Their brochure is an interesting account of a local epidemic of cholera and of its management.

#### BOOKS, ETC., RECEIVED.

Dissections Illustrated. A Graphic Handbook for Students of Human Anatomy. By C. Gordon Brodie, F. R. C. S., Senior Demonstrator of Anatomy, Middlesex Hospital Medical School. etc. With Plates drawn and lithographed by Percy Highley. In Four Parts. Part I. The Upper Limb. With Seventeen Colored Plates, two thirds natural size. Pp. iv-34. Part II. The Lower Limb. With Twenty Colored Plates, two thirds natural size, and Six Diagrams. Pp. 36-74. London and New York: Whittaker & Co., 1894. [Price, \$4.50.]

Venereal Memoranda. A Manual for the Student and Practitioner. By P. A. Morrow, A. M., M. D., Clinical Professor of Venereal Diseases in the University of the City of New York, etc. New York: William Wood & Co., 1894. Pp. iv-332.

The Diseases of Personality. By Th. Ribot, Professor of Comparative and Experimental Psychology in the Collége de France. Chicago: The Open Court Publishing Company, 1894. Pp. 157.

The Johns Hopkins Hospital Reports. Report in Gynæcology, II. Baltimore: The Johns Hopkins Press, 1894. Pp.

Bilateral Cerebral Thrombosis due to Syphilitic Arteritis, with Incontinence of the Vesical and Anal Sphincters. By J. T. Eskridge, M. D., Denver, Col. [Reprinted from the Medical News.]

Tumors of the Cerebellum. Clinical Lecture delivered at the Arapahoe County Hospital. By J. T. Eskridge, M. D. Denver, Col. [Reprinted from the International Medical Magazine.]

The Pathology, Symptomatology, and Treatment of Hæmorrhoids, Simple and Complicated. By Thomas H. Manley, M. D. [Reprinted from the St. Louis Medical Review.]

Surgical Therapy of Rectal Cancer. By Thomas H. Manley, M. D. [Reprinted from Merck's Bulletin.]

The Suprapubic Removal of an Enormous Vesical Calculus, together with the Pathology of Stone in the Bladder. By Carl V. Vischer, M. D., Philadelphia. [Reprinted from the Hahnemannian Monthly.]

The Relations of Urinary Conditions to Gynæcological Surgery. By Charles P. Noble, M. D. [Reprinted from the American Medico surgical Bulletin.]

The Causation of the Diseases of Women. By Charles P. Noble, M. D., Philadelphia. [Reprinted from the International Medical Magazine.]

Report of a Year's Work in Minor Gynæcological Surgery in the Kensington Hospital for Women, Philadelphia. By Charles P. Noble, M. D. [Reprinted from the Transactions of the Philadelphia County Ledical Society.]

Fibro-myoma of the Uterus and Broad Ligament of Forty-five Years' Duration. By Thomas H. Manley, M. D. [Reprinted from the American Gynacological Journal.]

Surgical Treatment of the Tumors of the Neck. By Thomas H. Manley, M. D. [Reprinted from the Medical Brief.]

Cocaine Analgesia in the Treatment of Hæmorrhoids, of Ulcers, Fistulæ, and Fissures in the Ano-rectal Region. By Thomas H. Manley, M. D. [Reprinted from the Medical Brief.]

Non-malignant Tumors of the Larynx. By W. Scheppegrell, A. M., M. D. [Reprinted from the New Orleans Medical and Surgical Journal.]

Comparative Microscopical Studies of the Ovary. By Francis Foerster, M. D. [Reprinted from the American Journal of Obstetrics.]

How shall we make our Homes Healthy? By Benjamin J. Portugaloff, M.D. [Translated from the Russian.]

Fifteenth Annual Report of the Trustees of the Binghamton State Hospital, at Binghamton, N. Y., for the Year ending September 30, 1893.

Eighth and Ninth Annual Reports of the Animal Industry for the Years 1891 and 1892.

Ueber Salipyrin. Von Professor Dr. von Mosengeil, Bonn. [Sonder-Abdruck aus Deutsche Medizinal-Zeitung.]

Report of the Kensington Hospital for Women, from October 10, 1892, to October 9, 1893.

Report of Two Years' Work in Abdominal Surgery at the Kensington Hospital for Women, Philadelphia. By Charles P. Noble, M. D. [Reprinted from the *International Medical Magazine*.]

Preliminary Report of the Income Account of Railways in the United States for the Year ending June 30, 1893.

# Miscellany.

Exophthalmic Goitre as a Sequel of Influenza; Strophanthus as a Remedy; and the Effects of Overdoses of Thyreoid Extract.—At a meeting of the Victorian Branch of the British Medical Association held on November 15, 1898, Dr. R. L. McAdam read a paper in which he gave the history of a case of exophthalmic goitre that had seemed to be the sequel of an attack of influenza in a girl sixteen years old. A report of the proceedings is given in the December number of the Australian Medical Journal. For several months treatment of the exophthalmia was unsatisfactory, and in a consultation it was suggested that one of the tonsils, which was unhealthy, be removed, and that was done. Dr. McAdam continued as follows:

"I saw no more of the patient till over two months had elapsed. Then, about the middle of March, she returned to her home, and once more put herself under my care. The effect of the treatment hitherto pursued had been disappointing, and almost nil. Practically, the status quo ante was still maintained, though she complained now of palpitation, and I found a well-marked systolic apical murmur present. I determined to make yet another alteration in the treatment, and, while still continuing the faradism, I began to give her tincture of strophanthus. The preparation used was Burroughs, Wellcome & Co.'s, made according to Professor Frazer's formula. The initial dose was my in water three times a day. By gradual increments, I got the dose up to Mxv thrice daily. This quantity she continued to take for many months, without the slightest appearance of toxic symptoms. Within two weeks after commencing the use of the strophanthus a change for the better became manifest; the rapidity of cardiac action lessened. the prominent eyeballs retreated, the thyreoid decreased in size, the tremors diminished, sleep became natural, appetite improved, the patient felt able for more exercise, she began to put on flesh, in fact, a general amelioration of her condition was unmistakably evident. In three months she increased two stone in weight. Toward the end of April, however, she became anæmic, and I gave her Blaud's pills in conjunction with the strophanthus, with satisfactory results. As time rolled on, the patient steadily improved, and in July menstruation recommenced, after a cessation of eight months. On several occasions I caused the strophanthus to be discontinued for a little while, and each time the old troubles began to reappear, to subside, however, on resuming the drug. Finally, in November last, I felt justified in pronouncing the patient cured. At that time she was in first-rate health; she could play tennis, take long walks, enjoy dancing, and, in fact, engage in all the exercises to which she had formerly been accustomed. In October

and November, coincidently with the menstrual period, a curious condition was manifested in the patient's eyelids. They became swollen, painful, and discolored, apparently from an exudation of blood-stained serum subcutaneously. Upon the subsidence of the swelling, which occurred in the course of three or four days, the usual oxidation changes which are found in an ordinary ecchymosis in that region took place. I mention the phenomenon, because I do not remember to have met with it, can find no reference to it, and am somewhat in doubt as to how to explain or account for its occurrence.

"About a year has now elapsed since I ceased attending Miss F. During that time she has continued in excellent health and spirits. A few weeks ago I had the opportunity of again examining her, and found that her condition was in all respects satisfactory. One interesting circumstance particularly struck me as evidencing how complete a change had taken place. I mentioned that while ill the patient's singing voice had almost entirely failed. Now, I was informed, it was remarkably good, and she was singing better than ever before, and with greatly increased breathing power. Her chest expansion had increased to between two and three inches.

"This case is worth recording, I think, for several reasons: First of all, it is fair to infer that the patient's attack of influenza was in some way concerned in bringing about the subsequent train of symptoms which justified the diagnosis of Graves's disease. Additional evidence that influenza can act in this way was recently afforded me by a patient who sought my advice for dyspepsia. On inquiring into her history, it appeared that a year before she had been attacked by influenza. Following this, there quickly occurred symptoms which, from her description and that of the friend who accompanied her, there could be little doubt were due to a mild form of Graves's disease. Secondly, it is not often that one has the satisfaction of seeing so entire a recovery from this distressing and frequently fatal trouble-a recovery, too, which was so comparatively quick in its occurrence. Thirdly, the history affords ground for thinking that in stropbanthus we have a drug which is well worth trying under similar circumstances.

"Permit me, in conclusion, to use this case as a peg on which to hang a few remarks as to the causation and nature of the strange affection of which it is so good an example. Some time since, while reading the accounts of the treatment of myxædema by thyreoid extract, I was much struck with the similarity between many of the phenomena produced by overdoses, and symptoms which one finds in Graves's disease. Here are some of the records to which I refer: G. R. Murray found that following a rapid injection of thyreoid extract there occurred flushing, nausea, and pain in the lumbar region. Another observer notes that as the result of too rapid absorption of the extract, tremors and quivering of the limbs developed. Sims Woodhead was struck with the fact that in rabbits peculiar effects were produced on the heart, and that these frequently culminated in degeneration of the muscular tissue of the organ. Again, in a myxædematous patient of Hector Mackenzie's, overdoses administered by the mouth caused anorexia, a pulse of 116, and on one occasion a rise of temperature to 100° F.

"Similar experiences might be multiplied, but the foregoing will suffice. Now, many years ago in England, Mr. (now Sir John) Simon suggested that the function of the thyreoid gland consisted in secreting some substance which was necessary for the nutrition of the nervous system. This idea has in recent years been remarkably verified. But may we not proceed further still, and, in the light of the knowledge we now possess, hold that, while the thyreoid secretion in normal quantity is a sine qua non of healthy nervous action, its presence in superabundance is, on the contrary, harmful and injurious in a high

degree? May we not, in fine, maintain that in an overactivity of the thyreoid gland is to be found the true cause of Grave's disease? Such a view seems to me to be eminently reasonable and worthy of acceptance, and it has recently derived fresh support from the success which has followed in this affection on partial removal of the gland. At any rate, such a pathology is, I take it, far more likely to be true than the vague, unsatisfactory, and even contradictory theories which have hitherto been propounded."

Interstitial Injections of Iodine in the Treatment of Goitre.-Dr. Georges Mangin, an interne of the Paris hospitals. contributes an article on this subject to the Gazette médicale de Paris for January 13th, in which he gives the details of the procedure as practiced by Dr. Duguet. These injections, he says, may be employed in any case of goître, but they are especially appropriate in those of medium size, of comparatively recent formation, fleshy, not much indurated, and not yet calcified, whether they are cystic or not. This little operation succeeds best in hydatid cysts of the thyreoid body, which are always cured by a single injection. Contraindications are: Albumin or sugar in the urine, the existence of the menstrual flow, exophthalmic goître, cancerous goître, and a cystic goître containing blood (only a relative contraindication). Accidents in this treatment have occurred to certain operators only because they have not strictly followed the letter of M. Duguet's instructions. Before undertaking the operation certain precautions should be taken. The patient's urine should be examined; it should be ascertained if she is menstruating; and the neck should be measured immediately above the goître, around it, and below it, and this measurement should be repeated before each injection. Various liquids have been tried, but none is so good as pure tincture of iodine. The needle of the syringe should be of steel or of irido-platinum, and it should be very sharp. After being used it should be cleansed in a very weak solution of ammonium chloride or potassium iodide, and then left until it is to be used again in a ten-per-cent. oily solution of carbolic acid. This having been done, it is necessary to determine the most appropriate point for inserting the needle. The operator should assure himself that the tumor has no souffle and that it presents no expansile movements; then he should palpate it carefully to find the central, fleshy, least resistant part, as far as possible from the large veins which sometimes ramify over its surface and also from any arterial pulsations. Into that point he should plunge the needle. The syringe is to be filled with tineture of iodine and the air expelled. Then the operator raises the patient's head in such a way as to make the throat prominent, holds the tumor immovable between the thumb and forefinger of the left hand, compressing it gently. with the right hand plunges the needle slowly to the depth of from half an inch to an inch, and waits to see if any liquid escapes through it. If pure blood flows, the procedure is to be stopped, the needle is to be withdrawn, and an attempt made to introduce it in one or two other situations, until one is found from which there is no flow of blood. If this can not be done. the idea of administering the injection must be given up for the time being. If a coffee-colored or a chocolate-colored liquid flows, the syringe should be connected with the needle, and, if the cyst is small, the liquid aspirated, and then the injection proceeded with. If, on the contrary, the cyst is large, slow aspiration should be performed with a regular aspirator. In case the injection is to be proceeded with, the syringe filled with tincture of iodine is to be connected with a needle and the piston pushed down very gently and slowly, while the operator observes the patient's face and interrogates him as to his sensations. At the first injection not more than half or three quarters of a syringeful should be injected. When the injection has been made, the needle, still connected with the syringe, is to be withdrawn rather suddenly; then the left forefinger is to be placed over the puncture in order to stop the slight discharge which might occur. If the patient's neck or the operator's hands have been soiled by the tincture of iodine, they should be washed in ammonia water. Usually nothing special occurs as the immediate result of these injections, but sometimes there is observed local heat, with tumefaction, a little embarrassment of the movements of the neck and in swallowing, and occasionally some painful sensations about the jaw, the teeth, or the ear of the side on which the injection has been made. These are benign phenomena, and do not last more than a day or two. They constitute no reason for not repeating the injection weekly, as should be done. Occasionally there is feverishness, with chills, headache, depression, agitation, sleeplessness, and gastric disturbance, symptomatic of a slight degree of acute iodism, which usually does not last more than from a few hours to a day or two. The author closes with the statements that this method of treatment acts by causing absorption and a non-suppurative inflammation, and that it is absolutely harmless and of marvelous efficacy when it is employed early and with discern-

Guaiacol as an Antipyretic .- The Medical News for January 27th publishes a portion of a lecture delivered at the Pennsylvania Hospital on January 13th by Dr. J. M. Da Costa, of Philadelphia, entitled Clinical Remarks on the External Use of Guaiacol in reducing High Temperature in Typhoid Fever and other Febrile Diseases. Dr. Da Costa thinks that the action of guaiacol is somewhat inferior to that of the cold bath as regards promptness, but he has observed that the reduction of temperature which it produces is more lasting. He thinks it preferable to the use of cold baths, particularly in cases where proper appliances for administering the baths are wanting and where from the nature of the case it is particularly objectionable to move the patient. The odor of guaiacol is an objection to its use, and this Dr. Da Costa has not yet been able to overcome. Oil of bergamot has been tried, but the odor of guaiacol overcomes that of the bergamot. Cologne water and oil of sassafras also have been tried, but the best result has been obtained with oil of cloves. Guaiacol is to be rubbed upon the skin of the abdomen or thigh with a camel's-hair brush over a space previously washed with soap and water. The largest amount that has been applied at once in Dr. Da Costa's experience is sixty drops, but from the application of fifty drops he has witnessed effects that cause him to advise that rarely should so large a dose be used. Thirty drops he thinks about the average dose. The guaiacol is to be rubbed in slowly, and the surface to which it is applied need not be uncovered, for the application can be made under the bedelothing, and it is well to cover the surface with a piece of lint and with waxed paper. The dose should be proportionate to the height of the fever; with a temperature of 103° F. it should not exceed twenty minims at the first trial. It is not necessary to rub the guaiacol in, but if friction is not used the effect is neither so rapid nor so complete. The quickest way is to paint the guaiacol on the surface and then rub it in with the hand. Five minutes are enough for the purpose. The sensation, which is not unpleasant, is likened to that produced by the application of menthol. Dr. Da Costa thinks that guaiacol is absorbed by the skin and that it is carried by the circulation to the heat centers, upon which it acts as an antithermic. Apparently its action does not involve the depression that follows the use of antipyrine, phenacetine, and other remedies belonging to the coal-tar products. Moreover, it produces less sweating. In no instance under Dr. Da Costa's

observation was there any albumin in the urine or any sign of kidney irritation detected that could be imputed to the use of guaiacol; nevertheless, he advises close examination of the urine in all cases in which the remedy is used.

The Antipyretic Action of External Applications of Cocaine. At a recent meeting of the Societi des sciences médicales de Lyon, the proceedings of which are reported in the Lyon médical for January 14th, M. Gelley, a hospital interne, made a communication on the antipyretic action of cocaine applied to the skin. In Professor Teisser's service a nurse had been directed to make applications of guaiacol to a number of feverish patients. Having one day used by mistake a solution of cocaine, he reported that he had taken the wrong bottle, but the patients' temperature curves nevertheless showed a reduction. Systematic trials were then begun and M. Teisser was able to observe that a reduction of several degrees was produced if care was taken to make the applications at a time when the temperature was no longer rising. The effect upon the general condition was apparently the same as when guaiacol was painted on. The patient experienced a sensation of repose and well-being, but the course of the disease was not modified. The procedure is the same as with guaiacol. A solution of from three quarters of a grain to a grain and a half of cocaine in a quarter of a teaspoonful of water should be used for each application, and the solution is to be applied to the upper part of the thigh. The antipyretic action of the application of cocaine is analogous to that of the application of guaiacol, but it is a little less energetic. M. Guinard reported that he had repeated these experiments on rabbits. He had resorted to the use of a cocainized ointment, the use of which was easier, but he had satisfied himself that unmedicated ointment was incapable of producing any reduction of temperature. With the cocainized ointment, on the other hand, he had caused a reduction of nearly 2° F. He thought it demonstrated that the medicaments employed acted upon the peripheral nerves.

The Antiseptic Action of Diaphthol.—In the Revue générale de clinique et de thérapeutique for January 17th there is a letter in which the writer remarks that M. Guinard has been making a critical and experimental study of diaphthol, which is the orthoquinolinemetasulphonic acid of chemists. It is a powder, fusible at 295° C. and capable of being crystallized in the form of brilliant needles which are colored green by perchloride of iron, and not by contact with metallic iron. By its decomposition it sets oxyquinoline free. With an alkaline solution it forms soluble diaphtholates. The diaphtholate of sodium in a ten per-cent. solution kills the Bacillus pyogenes fætidus and the Staphylococcus pyogenes in thirty or fifty minutes. In a five-per-cent. solution it only weakens their virulence.

Diaphthol is not very poisonous. The urine of animals which have ingested it rarely undergoes ammoniacal fermentation; nevertheless, it becomes putrid. In experiments recently made, it has been ascertained that the liver of these animals is preserved a long time without decomposition; therefore it is a substance which is opposed to certain fermentations. Add to these essential qualities the fact that this remedy is well borne by the gastric and intestinal mucous membranes, and it is easy to understand the interest shown in the use of diaphthol as an internal antiseptic, and especially as an antiseptic of the urinary passages, as it is eliminated free by the urine.

Bernheim's Nutritive Enema.—The Union médicale gives the following formula: Concentrated bouillon, ten ounces; pulp of boiled meat, an ounce; Malaga wine, six drachms. Such an enema, administered every three hours, it says, is sufficient to maintain nutrition.

# THE NEW YORK MEDICAL JOURNAL, FEBRUARY 17, 1894.

### Mectures und Addresses.

# LECTURES ON THE DIAGNOSIS OF ABDOMINAL TUMORS.

By WILLIAM OSLER, M. D., PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

LECTURE II.—NODULAR AND MASSIVE TUMORS OF THE STOMACH.

WE considered in the first lecture the cases in which the tumor was formed by the stomach itself, either in a state of extreme dilatation or extreme contraction. In twenty-one cases of the series nodular growths or diffuse thickening and infiltration were present; in three instances a massive infiltration. And first let me remind you of one or two anatomical facts. The only fixed portion of the stomach is the cardiac orifice, which is covered deeply by the left lobe of the liver, and externally corresponds to the seventh left costal cartilage near the sternum. The organ itself varies much in position with the degree of fullness or emptiness. The pylorus may be in the middle line, but when the organ is distended it is from six to eight centimetres to the right. It is usually, not always, covered by the liver. Fully two thirds of the stomach lie beneath the ribs in the left hypochondrium, and in contact with the abdominal walls are only part of the body and the pyloric region. Practically, however, we find that the organ is often depressed and so enlarged that a much more extended area than usually stated is exposed for palpation. Tumors limited to the cardiac orifice can not be felt at all, even when extensive. Those of the fundus and the posterior wall, and a considerable part of the lesser curvature, can only be felt when of large size. Tumors of a considerable extent of the greater curvature and a large section of the anterior wall are in accessible situations. It is of interest here to note the situation of new growths in the stomach, as determined in thirteen hundred cases analyzed by Professor Welch. The distribution was as follows: Pyloric region, 791; lesser curvature, 148; cardia, 104; posterior wall, 68; the whole or greater part of the stomach, 61; multiple tumors, 45; greater curvature, 34; anterior wall, 30; fundus, 19-so that at least three fifths of all tumors occupy the pyloric region.

The cases which have been under observation may be grouped into tumors at the pyloric region, tumors of the body of the stomach, and massive tumors occupying a very large area of the organ.

(a) Tumors of the Pyloric Region.—Of the twentyfour cases, there were seventeen with a tumor mass of some size or form to be felt at the distal portion of the organ. In ten of these dilatation of the stomach was present, prominent enough to itself cause a tumor and have been considered in the first lecture.

Before entering upon a description of the cases an important question arises: Is the normal pylorus palpable? It may be answered, I think, in the affirmative, with certain qualifying conditions. The pylorus forms a definite ring-

like muscular valve, readily to be seen and felt in the exposed organ. Whether, as has been stated, it relaxes and contracts rhythmically at definite intervals has not been fully determined, but I would remind you of the statement made by Beaumont, in his experiments on the movements of the stomach of St. Martin, that when the thermometer was placed toward the pyloric orifice it was at first firmly grasped, and then, by gentle relaxation, allowed to pass. If the stomach be exposed in a cadaver and a couple of towels laid upon it, on palpation over them the pyloric ring is readily felt. So also, I believe, it may sometimes be detected during life. Though normally covered by the anterior margin of the liver, it is freely exposed in a very considerable number of cases, and when the stomach is depressed or in a state of atony the pyloric ring is always below the edge of the liver. In persons with very thin walls, particularly in cases of enteroptosis in women, palpation in the boundary of the epigastric and umbilical regions may discover a small, transversely placed body, varying in position, with respiration which sometimes gives the impression of a structure alternately in contraction and relaxation. In some cases it may even be rolled beneath the finger. At intervals gas is felt to bubble through it. From the pancreas, which is also sometimes palpable, it is readily distinguished by the alternate relaxation and contraction, and by the bubbling of gas through it. The condition is one of some importance, as it may lead to the suspicion of gastric cancer. Thus I saw with Dr. Salzer, in September, 1892, a woman aged thirty two, a chronic dyspeptic, but who lately had had very severe symptoms, and had lost rapidly in weight, having fallen from ninety-five to sixty pounds. At the junction of the epigastric and umbilical regions, a little to the left of the middle line, there was a soft, cylindrical structure, which descended with inspiration. Its transverse extent was not more than three or four centimetres. It hardened definitely under palpation. Gas was felt escaping through it. The patient was, of course, extremely emaciated, and the discovery of the tumor, together with the pronounced stomach symptoms, led to a suspicion of malignant disease. The case was subsequently under my care for seven months, and proved to be an extremely obstinate form of anorexia nervosa; but she gained in weight from sixty to a hundred and fifteen pounds, and the improvement continues to date.

I believe that in very thin-walled persons, particularly those with atony of the stomach, the pylorus, i. e., the ring and adjacent part, may sometimes be felt as a narrow, tubular structure, the distinguishing features of which are the alternate relaxation and contraction and the bubbling of gas through it.

Of the seventeen cases, two were instances of cicatricial thickening and stenosis, and in fifteen there was either a cylindrical tumor or a nodular mass.

A tumor like formation at the pylorus may be due to a number of causes—cicatricial contraction and thickening about an ulcer, hypertrophy of the pylorus, and cancerous growths—all of which conditions may lead to stenosis of the orifice and secondary dilatation of the stomach. Again, the first part of the duodenum and the pylorus may be invaded by growths from contiguous organs, as in a case to be subsequently mentioned, in which the tumor in the pyloric region was caused by invasion of the duodenum by a cancer of the colon. And, lastly, there may be mentioned as a cause of dilatation of the stomach, stenosis of the pylorus by dislocation. Thus adhesions may form between the gall bladder and the pylorus, and this portion of the organ is drawn up and the orifice narrowed. A remarkable instance of the kind was operated upon in the hospital by Dr. Finney in August last.

Tumors of the pylorus are usually, but not always, associated with dilatation; thus there were only four out of the seventeen cases in which the organ was not distended. The cases of pyloric growths or thickening may be grouped as follows:

Thickening and Induration from Healing of an Ulcer.— Two cases come in this category—Case X of the series already given in the first lecture, which presented a very greatly dilated stomach. There was a ridge-like mass, freely movable, to be felt midway between the umbilicus and the right costal margin. The prolonged history of dyspepsia, the moderate wasting, the fact that she had on several occasions vomited blood, and the small size of the pyloric tumor, suggested cicatrization about an ulcer. In the following case gastro-enterostomy was performed by Dr. Finney, and, unfortunately, on the tenth day the patient died of an acute colitis. The nodular tumor was very well defined, particularly after the stomach had been emptied.

Case XII. Dilated Stomach; Tumor Mass at the Pylorus; Gastro-enterostomy; Autopsy; Stenosis from Uleer.—Mary G., aged twenty-two, colored, admitted on July 29th, complaining of a "gnawing in the stomach" and "vomiting spells." Family history good. Was healthy as a young girl, with the exception of a slight attack of pneumonia about eight years ago, and malaria a year later.

Her present illness began last April with loss of appetite and weakness, and she began to lose flesh. About two months ago she noticed a lump in the abdomen, which she thinks has got larger. About this time she began to vomit at irregular intervals, without any nausea or acid eructations. The attacks gave her relief, and she says the lump seemed smaller after them. The vomitus was copious, greenish in color, and watery. Bowels have been constipated. The feet have swollen sometimes. She has never vomited blood.

Condition on Admission .- Medium-sized, greatly emaciated, lips and mucous membranes pale, tongue presents a whitish fur. Pulse 92, regular, of fair volume. With the exception of a soft systolic murmur at the heart apex, there are no abnormal physcal signs in the thoracic organs. The abdomen is symmetrical, not specially distended. In the right hypochondrium, just below the costal margin and opposite to the cartilage of the eighth rib, there is a small nodule, apparently the size of a horsechestnut, which descends with inspiration and gives the impression of being at the pyloric orifice. It varies somewhat in position and in firmness; thus the day on which I examined her (September 1st) it could by no means be satisfactorily determined, although the day before Dr. Thayer had been able to feel it with the greatest distinctness. On inflating the stomach, the area of gastric tympany was found to be greatly increased, extending from the fifth rib above fully three fingers' breadth below the umbilicus. During great distention of the stomach

the nodular mass could not be felt. The material obtained after a test breakfast was mixed with fragments of undigested bread and curds of milk which had been taken the day before. It has a strong sour smell, suggesting butyric acid. The reaction was acid. The congo and tropæolin tests were negative. Uffelman's test gave sharply positive results.

After treatment for some time with washing out the stomach no special benefit followed, and, as the lesion seemed most probably stenosis from ulcer, it was thought advisable to attempt dilatation. Accordingly, Dr. Finney made an exploratory examination and found externally much thickening about the pylorus. He opened the stomach on the anterior wall, and, exploring digitally, found the orifice much narrowed, partly by contraction, partly by polypoid excrescences, several of which were removed. As it was doubtful whether this would be sufficient, a communication was made between the stomach and the jejunum. The patient did very well for ten days, but then vomiting and diarrhœa set in and the latter became severe and she died in the third week after the operation.

The post-mortem showed chronic adhesive peritonitis about the pylorus and over the surface of the liver. The jejunum was very firmly adherent to the anterior wall of the stomach. The tumor mass which had been felt during life was the thickened pylorus. When laid open, a large ulcer was found in the pyloric region with much puckering of the mucosa about it and cicatricial contraction.

Tubular and Small Nodular Tumors at the Pylorus.—Next let me call your attention to four cases which have presented a good deal of difficulty in diagnosis, not as to the existence of the tumors, but as to their nature. In three there was a cylindrical, somewhat tubular-shaped tumor to be felt. In two of them there was evidence of some dilatation of the organ after inflation, but the symptoms in each case were those of chronic dyspepsia, not of extreme dilatation of the stomach. I will first read you the report of the cases.

Case XIII. Chronic Dyspepsia; Cylindrical Tumor of the Pylorus.—Mr. S., aged seventy years, was admitted to Ward C October 6th, complaining of dyspepsia.

The patient has been a dyspeptic ever since 1843, and unless very careful with his diet had fullness and tenderness in the epigastrium. He frequently had very disagreeable feelings after eating, and would vomit or regurgitate the food. In spite of the dyspepsia, he has always been robust and has never been laid up in bed. For the past two years the dyspepsia has been more troublesome and he has frequently had pain after eating. The gastric trouble increased so much that four months ago he had to take peptonized milk. There has been no vomiting, though at any time he could regurgitate the food. For the past ten months he has lost in weight (as much as twenty pounds) and in strength, and has been in very low spirits.

The patient is a well-preserved man for his years, of spare habit, but neither emaciated nor cachectic. The general physical examination is negative. The heart, arteries, and lungs are normal.

Abdomen flat, on palpation soft, no pain. Four centimetres above the navel there is to be felt a ridgelike tumor, which can be rolled beneath the fingers, and which extends six centimetres in the transverse direction. On inspiration it descends slightly. It can be moved up and down; the surface is smooth, and firm pressure is not painful. The point of greatest interest is the remarkable variability in consistence within a few minutes. At times it is firm, hard, and ridgelike, and

within a minute it becomes very much softer. Gas can be felt to bubble through it.

There is no glandular enlargement. After a test breakfast sixty cubic centimetres of a light greenish fluid, rather slimy and mucoid, were removed, which gave none of the reactions for free hydrochloric acid.

Patient left hospital on October 22d, somewhat better, but I hear from Dr. H. M. Thomas that he died before Christmas.

Case XIV. Dyspepsia of a Year's Duration; Cylindrical Tumor of Pylorus.—Bertha N., aged forty-four, admitted to ward G, October 28th, complaining of pain in the epigastric region and loss of appetite.

Father died of tuberculosis; mother, of hæmorrhage from the uterus. She has had two healthy children.

Her present illness is of more than a year's duration. She has had weakness, loss of flesh, and for several months the appetite has been very poor. She gives an account of what she calls spasms, which would appear to be fainting fits at the menstrual period. After eating she has pain and has to lie down, and finds relief by pressure on the abdomen. There has been no vomiting. Lately she has lived principally on milk.

Present Condition.—There is uniform pigmentation of the face except in one or two spots on the cheeks and chin. The general pigment over the surface of the body seems to be somewhat increased, particularly on the abdomen and the arms. She is decidedly emaciated, but the lips are of a red color, and she has not a cachectic look. The tongue is furred. The examination of the thoracic organs is negative. The heart sounds are clear. The superficial arteries are slightly thickened.

The abdomen is flat, somewhat sunken, walls relaxed. In the epigastrium, a little below the ensiform cartilage and extending into the right hypochondriac region, a cylindrical tumor can be felt and rolled beneath the fingers; at intervals gas can be felt to bubble through it. The inflation of the stomach shows the organ to be depressed and somewhat dilated.

An hour after a test breakfast there was very little material obtained. It was acid to litmus paper; no reaction to congo paper. On washing out the stomach, two or three lumps of bread, not digested, were obtained. There was no free hydrochloric acid. Subsequent examinations showed persistence of this ridgelike mass in the epigastrium, but it varied considerably in position; thus on November 4th it could be felt distinctly to the left of the middle line, and even a ridge beneath the skin could be seen in this position to descend on deep inspiration.

The patient left the hospital December 22d, and has not since reported for examination.

CASE XV. Dyspepsia for Several Years; Cylindrical Tumor of the Pylorus.—M. O., aged fifty-four years, admitted March 10, 1893, complaining of pain in the stomach. Father died at sixty-two of pulmonary tuberculosis, of which disease also one brother died. Mother died at sixty-five of dropsy.

She has always been healthy; married; has three children. Has been subject to dyspepsia for several years.

Last winter she had a great deal of pain in the epigastrium, diarrhœa, and vomiting of a greenish fluid. She was in hospital for eleven weeks, but improved, and from July of last year until January she was perfectly well and could eat anything, but she has been paler and more sallow and has lost in weight.

The present trouble began about four weeks ago with pain in the epigastrium and great tenderness. She has had nausea, but no vomiting. The patient is a small woman, looks ill, complexion very sallow, lips and nuccous membranes pale. Tongue is flabby but clean. With the exception of a soft murmur at the apex of the heart, examination of the thoracic organs is negative.

The abdomen is a little full, everywhere tympanitic. There is a marked depression just below the costal margin on both sides; no peristalsis visible. Palpation at first caused so much tenderness that the examination was unsatisfactory; but as she drew a deep breath a small nodular mass could be felt descending beneath the ribs in the parasternal line. In a few days she was somewhat better, and a more thorough examination could be made. In the parasternal line, midway between the costa margin and the navel, there is a cylindrical mass, transversely placed, which can be rolled beneath the fingers. It is extremely sensitive; no flatus is felt passing through it. On deep inspiration, it descends and the fingers can be placed above it so as to hold it down. On percussion, it is resonant. After inflation of the stomach there is no marked dilatation of the organ; no peristalsis is seen, but the tumor is then not so easily palpable.

Ewald's test breakfast, withdrawn fifty minutes afterward, showed about fifty cubic centimetres of grayish, slimy fluid, containing portions of undigested food, and, on testing, no free hydrochloric acid.

Patient was under observation until May 11th. The tumor did not change in any way. The pain lessened and she gained in weight from a hundred and seventeen pounds on admission to a hundred and twenty-five pounds on discharge.

Case XVI. Nodular Tumor in the Pyloric Region; Dilatation of Stomach.—J. A. R., Talbot County, Md., seen October 19, 1892, with Dr. Chamberlaine. The patient had been admitted to Ward C, November 17, 1891, with the following history:

For ten months he had had occasional paroxysms of boring pain in the abdomen, coming on usually at night. Six months previous to admission he had noted a small nodular tumor in the abdomen, which he says has gradually become larger. He has had no symptoms of indigestion or special distention of the stomach after eating; has vomited only twice, on both occasions, he thinks, caused by a severe paroxysm of pain. He has lost about fourteen pounds in the past month. He was a man of spare habit, but was not anæmic. A test breakfast, withdrawn an hour after the meal, showed about two ounces of fluid containing small lumps of partly digested food. Free hydrochloric acid was present.

In the abdomen, just above and to the right of the umbilicus, there was felt a rounded tumor about the size of an Eng-

lish walnut, freely movable. On inflation, the stomach tympany extends two fingers' breadth be-

low the umbilicus.

The patient remained in hospital for a couple of weeks; had no special gastric symptoms, gained in weight, and returned to his home November 27th. The case was regarded as one of tumor of the pylorus, and he was told if the trouble increased an operation might be advisable.

October 19, 1892.—Patient examined to-day; has been very much better; entirely free from pain; has had no vomiting; has been taking an ordinary diet;

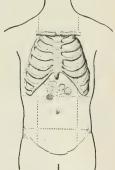

Fig. 13.—Positions into which the tumor could be moved in Case XVI.

no nausea; no sense of distress after eating. He looks and feels well.

The abdomen is a little full in the umbilical region, flat in

the epigastric. It is everywhere soft and painless; nothing can be felt in the epigastric region. Midway between the navel and right costal margin there is the same well-defined, firm, hard nodule to be felt, which is now painless. It de-cends with inspiration and can be moved about in the positions noted in the diagrams. The patient says that it is not nearly so evident when the stomach is empty. It is prominent enough to be seen when the skin is pressed over it. It can be pushed far up under the right costal margin and at first could not be felt, as it was high in this position and only made to descend by deep inspiration. To the left it can be pushed beyond the middle line to a point midway between the navel and the left costal margin. It is very mobile. On inflation of the stomach the lower border was found to descend some distance below the umbilicus-three or four fingers' breadth-while the lesser curvature was almost as low as the umbilicus. stomach was inflated the mass could not at first be felt, but afterward was found a trifle more to the right and not apparently quite so superficial as it was before the distention. Nearly a year has elapsed since this patient left the hospital; in that time the nodular tumor has increased but little in size, and the patient's general condition is remarkably good.

In Cases XIII, XIV, and XV the tumor had a definitely cylindrical shape, and in Case XIII there seemed to be no question that the tumor was a thickened pylorus, as marked variations occurred in its consistence and gas could be felt bubbling through it. So also in Case XIV similar fea tures seemed to indicate clearly that the tubular structure, so readily felt, represented in reality the thickened pyloric ring and adjacent part of the stomach. In Case XVI the tumor was rounded, nodular, and very movable. It did not vary in consistence and no gas was felt to bubble through it. It felt very hard and firm. While its local features seemed to indicate definitely that it was a new growth, the general condition of the patient after its existence for eighteen months seemed to be very much against the view that it was cancer. Scirrhus, however, may develop very slowly indeed at the pylorus, and make very slight progress within six months. Thus in Case XVII, on the first admission in September, after an illness of fifteen months' duration, the pyloric tumor constituted a tubular, sausage like tumor, which could be rolled beneath the finger. I frequently discussed with Dr. Thayer the question whether it was an instance of hypertrophic thickening of the pylorus or a scirrhus growth, and the time element seemed to be in favor of the former; but when the patient returned in April of this year the tumor, which meantime had increased in size, was found to be a scirrhus. The hypertrophic stenosis, with which the annular scirrhus of the pylorus could alone be confounded, occurs in connection with chronic gastritis, with scars of old ulcers, in connection with a cirrhosis in other parts of the stomach or intestines, and sometimes with a general sclerosis of the tissues of the mesentery and peritonæum. It may be impossible, for a time, to give a positive opinion. In either case, however, the condition is serious.

Cases of Large Nodular Growths at the Pylorus.—These constitute a large majority of pyloric tumors. Most of the cases have already been described in the first lecture in connection with the dilatation of the stomach. In some the tumor itself was visible beneath the skin. The follow.

ing cases are good illustrations of this type of growth. In one the tumor was an annular cancer, which was removed by operation:

Case XVII. Annular Carcinoma of the Pylorus; Excision of Growth; Death; Autopsy .- Henry M., aged sixty-one years, laborer, admitted September 30th, complaining of "sour stomach" and vomiting.

No history of hereditary disease. Patient has been healthy and strong, and has had only a few illnesses. He has used alcohol freely, but has not been a heavy drinker.

Present illness began fifteen months ago with an uneasy feeling in the abdomen and churning sensations, which continued until he vomited a watery, very bitter fluid, which sometimes had a greenish-yellow color. At first his appetite and digestion remained good. The uncomfortable feeling after eating gradually increased, and during the past five months, although his appetite has been good and he took his regular meals, vomiting came on about an hour and a half afterward. He has never brought up very large quantities, and pain has never been a prominent feature. He has lost weight rapidly, and within six months has fallen from a hundred and fifty to a hundred and fourteen pounds. The bowels have been very irregular, and he sometimes has had no movements for a week or ten days, and recently has gone as long as sixteen days.

Present Condition.-Large-framed man; much emaciated, particularly in the face. The cheek bones are prominent and the eyes sunken. The mucous membranes are not specially anæmic, and the facies can scarcely be termed cachectic. The emaciation is marked about the thorax; the skin is smooth and clean; superficial lymph glands are not involved. The tongue is a little swollen, indented, and furred.

The abdomen is flat, very much below the level of the costal margin. There is a slight prominence just to the right of the navel, and on deep inspiration a ridgelike mass descends below the point.

On palpation, there can be felt just above and extending to the right of the navel a firm mass which descends on inspiration

and can be rolled beneath the fingers, giving one the impression of a tubular, sausage-like tumor. On deep inspiration, it moves down nearly three inches and can be readily held at the navel, and then slips away from beneath the fingers.

The patient was placed upon a careful diet of milk and egg albumin, upon which the nausea disappeared and he became very much more comfortable. The examination on the 17th showed that the elongated mass above referred to had changed in position and lay to the left of and just above the navel.

The liver is not enlarged; Fig. 14.-a, position of the tumor in the edge of the spleen is not pal-

expiration; b, in inspiration.

The patient got dissatisfied with the diet, and left the hospital October 17th, though he seemed to be considerably im-

April 6, 1893.—Patient returned to the hospital, having had, in the space of nearly six months which has elapsed since the last note, very marked gastric symptoms and occasional attacks of vomiting of large quantities of fluid. He has lost in

weight, though he does not look much more emaciated than when he left.

Examination.—Abdomen is scaphoid and the walls held rather rigidly. Between the ensiform cartilage and the navel the solid rounded tumor present in September can be felt in the same position, but it appears definitely to have increased in size. It can be rolled beneath the fingers, and part of it at least varies somewhat in consistence, becoming harder and firmer. The stomach is moderately dilated, and when inflated with gas shows distinct peristalsis, and then the tumor is not nearly so evident.

The advisability of an operation was suggested to the patient in the autumn, but he refused; now he is anxious that one should be performed.

The age, the profound emaciation, and the very evident increase in the size of the tumor suggested cancer rather than cicarricial contraction, with thickening at the pylorus; and as the case was a desperate one, and the man's condition hopeless, the election of operation was left to the patient.

On the 11th Dr. Halsted operated and found a solid annular growth in the pylorus, extending for about seven centimetres, reaching to the orifice, but not extending into the duodenum. As there were no special adhesions and no nodules, he proceeded to resect the growth, which was done successfully. The operation lasted about two hours, and the patient was very much exhausted; he rallied well through the night and seemed very comfortable, but failed rapidly on the 12th and died on the 13th.

Case XVIII. Cancer of the Stomach; Large Tumor in the Pyloric Region.—Patrick K., aged twenty eight years, admitted to Ward E. January 3, 1893, complaining of pain in the abdomen. Patient had been an orderly in the hospital in 1889-'91, during which time he was laid up on several occasions—once in December, 1889, with voniting and diarrhæa; again in April, 1890, with acute gastritis, an attack associated with much pain; and in April, 1891, he had a sharp attack of amygdalitis. A very noticeable feature was the persistent anæmia, and on several occasions in 1889 and 1890 I had examined his blood, which presented all the characters of a secondary anæmia of moderate grade. From his earliest boyhood he has been subject to nose-bleeding, and has always, he says, been pale.

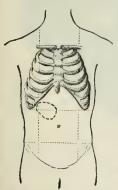

Fig. 15.—Situation of the tumor in Case XVIII.

In October, 1891, he returned to his home in Ireland, and remained fairly well, but was troubled on several occasions with epistaxis. He returned to this country last year. Four months ago he had an attack of pain in the abdomen with vomiting, and these symptoms have persisted ever since. The vomiting is chiefly after taking food, and the pain is also most severe at this time. He has never vomited blood. Bowels have been constipated. He has lost in weight, he thinks, as much as fourteen pounds. He is short of breath on exertion, and when he walks about for any length of time the feet and ankles swell.

Present Condition.—He is very anæmic, but not emaciated; his face is full; blood count, 3,000,000; hæmoglobin, thirty per cent.; eyelids a little puffy; hands very pale; pulse, 87, soft, compressible; radials a little thickened; vessels of neck throb; the heart sounds are loud and clear at the apex, the second very ringing and accentuated at the base; no murmur. The examination of the lungs was negative.

Abdomen full and a little prominent; on palpation, everywhere soft and painless until the right epigastric region is reached. Here, under the costal border in the perasternal line, there is a resistant mass which extends to the right almost as far as the middle line and to the left as far as the nipple line, and below at least six centimetres from the costal border. During a deep inspiration the mass descends and the fingers can then be placed between it and the costal margin. In the middle line in the epigastric region nothing is palpable. There is resonance over the above-described tumor mass. There is no peristalsis apparent; no gurgling to be felt in the mass. After dilatation of the stomach the tympany in the parasternal line was at the seventh rib, and extended two fingers' breadth below the navel. The tumor was pushed far over nearly beyond the nipple line.

A test breakfast withdrawn an hour after gave a hundred and twenty cubic centimetres of thick, dark-brown fluid, containing undigested food and a few shreds of clotted blood. The reaction was acid; there was no reaction with congo paper, nor with the other tests for free hydrochloric acid. Uffelman's test for lactic acid was positive; starch test negative. The spleen was not enlarged; the liver not enlarged. The urine presented no changes.

The patient failed rapidly, became very anæmic, and lost sixteen pounds in weight within a month. The vomiting was very troublesome and intractable. No special change took place in the character of the tumor mass, though as he became thinner it was rather more evident. He died on February 23, 1893. There was no autopsy.

Practically, then, the tumors at the pyloric orifice which we have been studying consisted of cicatricial thickening caused by ulcer, possibly hypertrophic stenosis, annular carcinoma, and large nodular masses. There are one or two points of general interest to which I will here refer. In the first place, the tumor is always larger than you expect from the examination through the abdominal wall. This has to be borne in mind in a discussion on the advisability of operation. It is frequently very variable-well and plainly to be felt to-day, and perhaps scarcely palpable tomorrow-variations which depend a great deal upon the degree of dilatation of the organ, particularly of the portion known as the pyloric pouch, which may cover over and mask even a large pyloric tumor. Examination in the knee elbow position often gives valuable information as to the relations and positions of a tumor, and should never be omitted in doubtful cases. The value of careful palpation with a view of determining whether gas bubbles through the tumor is of the very greatest importance. The masses are usually firm, hard, and often of a stony consistence; sometimes the nodular masses formed by the glands in the neighborhood of the pylorus can be very plainly felt. A feature in the pyloric tumor which merits special attention is the mobility. I have already referred to it in Case V, in which the solid rounded tumor mass could be pushed beneath the ribs on the right side, far down into the iliac regions, and far over to the left costal border. So also the nodular tumor in Case XVI, which I have just read to you, was extremely movable. I reported a case a few years ago

(University Medical Magazine, vol. i, p. 368) which is of great interest in this connection:

The patient, aged sixty-five years, was admitted to the Philadelphia Hospital, October 14, 1888, with chills and fever. The blood, however, was negative, and it was ascertained that he had had for some weeks distress after eating, and our attention was then directed to a more careful examination of the abdomen. On November 11th the following note was made: Patient is anæmic and emaciated; the abdomen flattened; there is a prominent projection below the left costal border in the parasternal line, reaching nearly to the navel and descending with inspiration. Palpation reveals a firm, hard mass, occupying the left hypochondriac region and the left half of the epigastric region. It is smooth and not painful, and can be moved from side to side to an extent of two or three inches. Percussion over it gives a flat tympanitic note; liver dullness not increased; glands in the groin are double the normal size; vomited matters are brownish in color, acid, but contain no sarcinæ. The tumor changed curiously in position from day to day; at one time it was far over in the right hypochondriac region, entirely beyond the middle line, but more commonly a greater portion of its extent was in the left hypochondriac region. On several occasions it seemed to have disappeared altogether, and only a hard, small mass could be felt far over in the left hypochondrium. Patient sank gradually and died November 20th. When the abdomen was opened no trace of tumor was visible until the stomach was pulled down and to the right. It was then seen that the mass had fallen back into the left hypochondriac region below the ribs, where it was completely covered by the splenic flexure of the colon. The duodenum was curiously elongated and straightened; from the pyloric ring it measured over two inches as a straight tube. The pancreas was also drawn over to the left. The tumor could readily be pushed to occupy the positions in which it was felt during life. It involved the anterior wall of the stomach, which, when opened, presented a large hemispherical mass, involving three fourths of the circumference of the pyloric region and extending to within an inch and a half of the ring. The surface of the mass was ulcerated, and at the base near the greater curvature suppuration had taken place.

(To be concluded.)

## Original Communications.

A CASE OF RETINITIS PIGMENTOSA, WITH EXTREME CONTRACTION OF THE VISUAL FIELDS AND WITHOUT NIGHT BLINDNESS.

By F. W. MARLOW, M. D., M. R. C. S. E., PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF STRACUSE, N. Y., ETC.

Miss K. L. C., aged twenty years, was brought to me early in February, 1898, by Dr. R. J. Dimon, of Hastings, N. Y., for examination of the eyes.

She stated that her symptoms had been present from her earliest recollection. She can only see what she is looking directly at. In looking at the face of another person five or six feet distant, she sees nothing but the face, neither at the sides nor above and below. While walking she always keeps her eyes on the ground to avoid stumbling. She has no more hesitation in going about at night than in the daytime, and thinks there is no more difference between her day and night vision

than is the case with other people. A dull light makes no difference in her ability to read small print.

Fig. 1.-Field of vision of right eye.

Examination showed R. V.  $= \frac{6}{6}$  partly — not improved by glasses.

L. V. = <sup>6</sup>/<sub>9</sub> partly—0.5 D cyl. 90° improves slightly. Reads 1 Jaeger easily.

Her ability to read small print in dull light was compared with my own in the dark room, with gradually diminished illumination, and showed no relative defect. Careful measurement of the field of vision with the perimeter showed the boundary of that of the right eye to lie between 5° and 7.5° from the fixation point in all directions, that of the left eye lying in most directions at 7.5°, in some slightly within that point. The accompanying outs show the outlines and size of the fields with tolerable accuracy. The ophthalmoscope reveals the presence of typical retinitis pigmentosa, and the deposits of pigment come within three disc-breadths of the papilla.

Frg. 2.-Field of vision of left eye.

Her mother thinks the patient's vision unchanged from earliest childhood, but specific statements made by the patient herself leave no doubt that definite, although probably slight, contraction of the fields has taken place within the last few years.

There is nothing in the obtainable history to throw light on the nature of the causation. She had scarlet fever at five years of age, but vision was defective before then, and her mother says that she always stumbled over things

on the floor. I was unable to learn of any eye trouble in the family. Consanguinity in the parents is out of court, the father being of French, the mother of Dutch-Scotch descent.

The history leaves little doubt that extreme contraction of the visual field was present very early in life, and, taking into consideration the extremely slow progress, it seems probable that the condition had its origin during the intrauterine period of life.

No treatment was advised. I report the case chiefly on account of the entire absence of the most characteristic symptom of the disease.

401 MONTGOMERY STREET.

#### THE EYE TREATMENT OF EPILEPTICS.

A ORITICAL REVIEW OF

CERTAIN FACTORS THAT MAY LEAD TO CONVULSIVE SEIZURES, AND THE TREATMENT OF EPILEPSY WITHOUT DRIGS.

BY AMBROSE L. RANNEY, A. M., M. D.

(Concluded from page 113.)

Case XVII.—Miss F., aged seventeen years. Referred to me December 28, 1891.

Family History.—Mother has hypermetropia and astigmatism and esophoria. No hereditary tendency to nervous diseases so far as known.

History of the Case.—When seven years old patient had three convulsions within six months. From that time she had no attacks until February, 1891, when she had another. Since then she has had one in April, one in September, and one in December. These attacks occur at the menstrual period and are always accompanied by nausea.

She has been examined by several physicians and no organic disease found.

Eye Defects.—Patient had \$\frac{9}{2}\$— vision under atropine and would tolerate no + glass. Her muscular tests on the first visit to the office were: Adduction, 25°; abduction, 8°—; sursumduction—right, 2°; left, 2°; no hyperphoria; esophoria, 3°. Within the next three weeks, after wearing prisms for the manifest esophoria (which were slowly increased in strength), she showed with a 4° esophoria prism: Esophoria, 5°; no hyperphoria; adduction, 38°; abduction, 5°—. In accommodation—esophoria, 10°.

Treatment and Results.—A graduated tenotomy was performed on the right internal rectus with an immediate result of exophoria, 0.25°; abduction, 10°. Six days later she showed: Adduction, 32°; abduction, 8°; no hyperphoria; no exophoria.

During the next three months the patient was seen very frequently, and prisms were tried for a suspected latent esophoria; but no esophoria was discovered. Her tests on May 3, 1892, three months after the operation, were: Adduction, 38°; abduction, 8°; no hyperphoria; esophoria, 0.5°; in accommodation—esophoria, 4°.

The results of treatment in this case were negative. She had one attack in February and another in July. At her last report she was having an attack about once in five months.

Case XVIII.—Miss J., aged twenty-two years. Referred to me October 13, 1890, by Dr. H. J. Dwinell, of Barton, Vermont.

Family History.—Mother has a high degree of hypermetropia. Father has marked exophoria. Paternal grandmother had ptosis. One paternal aunt has hysterical attacks resembling epilepsy. Maternal grandmother died of phthisis. History of the Case.—When patient was a baby, she had an eye that turned down at times so that the pupil could not be seen. When eight years old she began to have slight "fainting attacks," which steadily grew more frequent and of longer duration. About five years ago she began to have convulsions with contraction of arms, legs, and face, her head drawing to the right, with drooling at the mouth. She was at once put upon bromides and only averaged four severe attacks a year. At present she is not taking bromide and averages one attack a month.

Patient has a severe headache once a month and slight headaches between. She has always been a very nervous child and sleeps very poorly. She complains of a weak back, pain in her left shoulder, and a tickling in her feet and legs, which is very annoying.

Patient is very moody; is unable to do even light work about the house; and never goes out without an attendant.

Eye Defects.—At the first visit patient showed a crossed diplopia of 12° and a vertical diplopia of 2° with a red glass; vision \$\frac{2}{2}0\$ in each eye. Under atropine vision was \$\frac{2}{2}0\$ with + 1.00 s. Within two days she disclosed: Right hyperphoria, 5°+; exophoria, 18°; abduction, 20°. The other muscular tests could not be obtained on account of the extreme heterophoria.

Treatment and Results.—The treatment of this case consisted solely in graduated tenotomies for the correction of the heterophoria.

An operation was performed upon the right superior rectus; the following day upon the left external rectus; and six days later upon the right external rectus.

Three days after the last operation patient showed: Adduction, 25°; abduction, 5°—; sursumduction—right, 3°; left, 3°; no hyperphoria; exophoria, 3°. Patient was then sent home with instructions to report monthly, and to return in the spring to complete the treatment.

January 12, 1891.—Patient reports only two attacks since October 17, 1890. These were associated with menstruation. She has gained markedly in weight. Last attack December 12th.

March 6, 1891.—Patient's father states that she has had no convulsion since December 12, 1890—nearly three months. She has momentary flashes about a week before menstruation. She is much less moody, goes where she chooses without an attendant, visits places of amusement alone, and friends for a day at a time.

April 18, 1891.—A letter from her father says: "Our daughter has had no return of the disease since last note, not even a symptom or indication of the return of the disease since the last week in February. She sleeps without that movement of the muscles. The "disagreeable smell" which troubled her so much does not return; and she is free from aches and pains. No headache. All this without one drop of medicine since the 1st of October last."

September 24, 1891.—Patient returned to day for further treatment. She reports that only five severe attacks have occurred since last October, the last occurring on August 25th. She has had a number of attacks of petit mal since last attack of grand mal. Patient shows: Adduction, 23°; abduction, 6°; sursumduction—right, 2°; left, 2°; right hyperphoria, 0.25°; exophoria, 2°.

A full correction of her hypermetropia (+1.00 s.) was given for constant wear and her muscles exercised with prisms. In five days she showed: Adduction, 28°; abduction, 6°; sursumduction—right, 2°; left, 2°; no hyperphoria; no exophoria.

November 23, 1891.—A letter from her father says: "Our daughter is doing finely; only one attack or convulsion since

last August. Her general health is much better than when in New York. She works every day and has commenced to practice on the piano. We can see a great improvement from what she was before you saw her the first time."

March 12, 1893. — The father states in a letter: "My daughter is much improved since our visit to you in the fall of 1890, and, since October, 1891, she has had but three convulsions, and these not as severe as those she had before you saw her."

Case XIX.—Miss D., aged twelve years. Referred to me by Dr. T. J. Martin, of Buffalo, N. Y., on March 15, 1893.

Family History.—No hereditary tendencies to nervous disease so far as known.

History of the Case.—This patient had her first attack while teething, her second when three years old, her third when six years old, and her fourth when ten years old. In 1891 she began to have attacks every six weeks and was put on bromide. She then went eighteen months without an attack, and bromides were stopped, as the attending physician deemed it wise to discontinue them.

During the three months prior to her first visit to me she had four severe attacks of typical epilepsy. She is otherwise a strong, well-developed, healthy child.

· Eye Defects. — Under atropine patient showed: O. D. + 2.75 s.; O. S. + 3.25 s.; adduction, 25°; abduction, 6°; sursumduction—right, 2°; left, 2°; no hyperphoria; esophoria, 2°. Within a few hours, under the influence of esophoria prisms, she showed: Esophoria, 7.5°; abduction, 2°.

Treatment and Results.—The following glasses were given for constant wear with instructions to use atropine if ciliary spasm should occur: O. D. + 2·00 s., O. S. + 2·50 s. Graduated tenotomies were performed upon both interni within a week and the patient sent home for a few weeks.

May 5th.—Six weeks after the operation the patient returned for further treatment and her tests were: Adduction, 26°; abduction, 8°; sursumduction—right, 2°; left, 2°; no hyperphoria; esophoria, 0.25°. Her father reports that she has had but one attack (April 25th), which was lighter than usual. Nothing was done at this visit except to exercise her muscles with prisms.

November 27th.—Patient's mother reports that she has had five attacks since last April (a period of over seven months); that the attacks have been lighter, and the interval between attacks much longer, than prior to the eye treatment.

As she seemed to tolerate a stronger spherical glass, she was given: O. D. + 2 50 s., O. S. + 3 00 s. for constant wear. Her muscular tests were: Adduction, 25°; abduction, 8°; sursumduction—right, 3°; left, 3°; no hyperphoria; no exophoria.

Case XX.—Miss D., aged thirty years, single, bank clerk. Referred to me on June 15, 1893, by Dr. Clara E. Gary, of Boston, Mass.

Family History.—Mother has had violent sick headaches. Father has been a victim to "blind" headaches and eye trouble. Headaches are very common in maternal ancestry. One brother and two sisters died at two years of age—one from "water on the brain," one from meeingitis, and one in convulsions.

History of the Case.—From two to three years of age the patient "has always had something the matter with her stomach." When thirteen years old she began to have severe sick headaches, and these have continued ever since. Menstruation began at eighteen years of age. Two years later, during menstruation, she had her first epileptic seizure, and during the next five years she had four severe attacks.

Five years ago she had two attacks in one day, and was put on bromides, which she continued to take up to October, 1892. During these five years she had ten severe attacks, the interval between attacks varying from two months to a year.

Since the stoppage of bromides she has had two stacks one in March and the last one in April. All of her attacks are accompanied by total loss of consciousness, rigidity, frothing of mouth, slight contraction of muscles, and no aura.

Eye Defects.—Under homatropine the patient showed: Hypermetropia, +1'50s.; adduction, 37°; abduction, 5°; sursumduction—right, 3°; left, 3°; no hyperphoria; esophoria, 9°. After wearing a 4° esophoria prism for twenty-four hours her esophoria was 12°, her abduction dropped to 3°, and she had homonymous diplopia with the red glass.

Treatment and Results.—As the patient was able to remain in New York but three days, she was given +1.00 s.  $\bigcirc$  2° prism, base out, in each eye for constant wear, and was instructed to return as soon as possible for operation.

October 9, 1893.—Patient returned to-day for further treatment. She shows esophoria of 11° and abduction of 2°—.

Within a few days graduated tenotomies were performed upon both internal recti, and the prisms were removed from her glasses. Directly after the last operation she showed esophoria, 2°; abduction, 8°. One week later her tests were: Adduction, 38°; abduction, 6°; no hyperphoria; esophoria, 2·5°.

November 14, 1893.—Patient writes that she has had no epileptic seizure since last April (a period of over seven months), and has been doing her work at the bank regularly.

Case XXI.—Mr. T., aged twenty-two years, married, photographer. Referred to me on February 17, 1892, by Dr. Elmer Small, of Belfast. Me.

Family History—The father has severe sick headaches and "dizzy spells." Mother and two brothers are perfectly well. One paternal aunt has severe sick headaches. One paternal uncle has nervous prostration.

History of the Case.—Patient was a very strong child, but had momentary attacks of unconsciousness. When twelve years old he had his first typical epileptic seizure, with the epileptic cry, loss of consciousness, violent convulsive movements, and frothing at the mouth. He was at once put upon bromides, and they have been kept up ever since. He averages about six severe seizures a year; the shortest interval between attacks has been two weeks, and the longest nine months. During the past year he has also had several slight attacks of unconsciousness, lasting only a few seconds. Patient has always had some difficulty in using his eyes, and three years ago consulted Dr. E. E. Holt, of Portland, Me. Dr. Holt prescribed myopic cylinders, and cut both internal recti.

Eye Defects.—Under atropine patient showed +0.50  $\subset$  + 0.50  $\subset$ , axis 90°, in each eye; adduction, 40°; abduction, 6°; sursumduction—right, 2°—; left, 2°—; no hyperphoria; esophoria, 2°.

Within a week, by the use of esophoria prisms, the patient showed, while wearing 5° of prism: Esophoria, 7°; adduction, 60°; abduction, 1°.

Treatment and Results.—Patient was given hyperopic cylinders (+050 c., axis 90°) for constant wear. Later on this was increased to a full atropine correction.

A graduated tenotomy was performed on the left internal rectus, and five days after the operation he showed: Adduction, 56°; abduction, 8°—; no hyperphoria; esophoria, 1°.

Eince the last operation the patient has been seen at frequent intervals, and prisms have been given several times for suspected latent esophoria; but he has never manifested clearly any esophoria, and the prisms have been removed.

His last tests on September 25, 1893, were: Adduction, 50°; abduction, 7°+; no hyperphoria; esophoria, 0.5°.

All bromides were stopped from the time of his first visit (February, 1892). During the first year he had fourteen at-

tacks; but they have been steadily decreasing in number, so that for the past year he has had only six attacks.

This is the exact number that he had when under heavy doses of the bromide salts. The physical condition of this patient has improved greatly since the bromides have been withdrawn.

Case XXII.—Miss R., aged twenty-two years, single, referred to me October 24, 1893.

Family History.—Mother and two maternal aunts died of phthisis. Father has chorea and has had tenotomies performed on one internal rectus for esophoria. Chorea for at least four generations on the paternal side. Paternal grandmother and one great uncle committed suicide. Several cases of insanity among the paternal ancestors.

History of the Case.—When the patient was only a day old she was given an overdose of morphine. This caused convulsions, which lasted for several days. The child again had one convulsion during her second summer while teething, and not long after her eyes became markedly crossed. When five or six years old, tenotomies were performed upon both interni by the old-fashioned method, for the correction of this defect. Although nervous and irritable, she grew large and apparently well, developing early.

In her thirteenth year she began to have "attacks of sickness at the stomach, or perhaps sour risings." These continued to increase in frequency, and four years ago she was placed in care of a physician, who pronounced them attacks of petit mal. During the past four years the spasms have changed in character and become extremely frequent. The patient is very regular in her menstruation, but suffers from very annoying chronic constipation.

Eye Defects.—At the first visit patient showed: Vision, O.D. § 5 —; O.S. § 5 —, not improved by any glass; left hyperphoria, 5°; esophoria, 7° to 15°; extreme nystagmus when either eye is covered, but only noticeable at times when using both eyes. Her left eye rolled up very markedly when covered, and putting a red glass or the Maddox rod before either eye caused such marked nystagmus that those tests were impossible. I was also unable to determine the strength of her ocular muscles.

A 4° left hyperphoria prism was given and in thirty minutes she showed left hyperphoria of 9°. Under homatropine her vision in either eye was made  $\frac{2}{30}$  — by + 1·25 s. Binocular vision  $\frac{2}{30}$  —.

Treatment and Results.—The treatment consisted in the correction of her hypermetropia by glasses (+1 '00 s.) to be worn constantly, and a graduated tenotomy upon the left superior rectus. Immediately after the operation she showed 3° of left hyperphoria. Ten days after the operation she showed: Left hyperphoria, 1°; esophoria, 10° to 14°; and the eye did not roll up when covered. She was then sent home with instructions to report monthly and return later for treatment.

November 13, 1893.—A letter from her father states that she has had six attacks of petit mal during the past sixteen days. This is somewhat less than prior to the tenotomy.

The treatment of this case can hardly be considered as more than begun. The heterophoria is so extreme, that until further work is done upon the eye muscles, the nystagmus and the nervous symptoms will undoubtedly persist.

CASE XXIII.—Mr. M., aged thirty-one years, single, clergy-man, referred to me October 21, 1893, by Dr. A. A. Smith, of New York.

Family History.—Mother had severe neuralgia. Father and three brothers are all living and well. Maternal aunt had epilepsy. One case of insanity in ancestry.

History of the Case. - Patient was well and strong up to

eighteen years of age, when he had a "fainting attack." At twenty-four, while in college, he had his first regular epileptic seizure, after a hard night's work, during a class "rush." A few weeks later he had a second attack in presence of a doctor on a train. He fell with the epileptic cry, had marked convulsive movements, frothed at the mouth, was unconscious for twenty minutes, and very sleepy for hours afterward. At that time he was put on heavy doses of bromide and has kept it up pretty constantly ever since.

Three years ago he had attacks from one to three weeks apart, but last year only had four severe attacks. He always has his attacks in the morning and very often on the cars. Looking out of a car window always causes great discomfort.

Eye Defects.—Under homatropine the patient has  $\frac{20}{50}$  vision, but tolerates a +0.50 s. His muscular tests at the first visit were: Adduction, 23°; abduction, 4°; sursumduction—right, 2°—; left, 2°—; right hyperphoria, a shade; esophoria, 1°. Within a week, after wearing esophoria prisms, he showed, while wearing 6° of prism: Adduction, 35°; abduction, 0; no hyperphoria; esophoria, 7.5°. Unconquerable homonymous diplopia existed when the prisms were removed. Later, a very high degree of latent esophoria disclosed itself.

Treatment and Results.—The treatment of this case consisted of three graduated tenotomies on the internal recti muscles. One on each internus was performed within a week; and two weeks later the right internus was again buttonholed. Between these steps the patient was seen daily; his eye muscles were exercised with prisms; and prisms given as fast as he showed any esophoria.

Five days after the last operation he showed: Adduction, 41°; abduction, 6°+; no hyperphoria; no esophoria. All bromides were stopped on November 8th.

December 2, 1893.—Patient reports that he has had no epileptic attack. His eye tests are the same as last noted.

He was sent home with instructions to render a monthly report for three or four months.

There is reason to believe that some latent esophoria still exists; but I deemed it wise to allow the patient ample time to learn to use his eye muscles in their modified adjustment before I investigated the suspected but entirely latent heterophoria.

On January 3, 1894, a report was received from this patient. He says: "I have been entirely free from any epileptic seizures, and I find my head much relieved when at work. I can speak and write with a facility I have not known for years."

Case XXIV.—Master R., aged nine years, referred to me January 7, 1889, by Dr. J. W. Wright, of New York.

Family History.—Both parents are living and healthy. A brother has severe headaches. Several cases of phthisis and cancer have developed in maternal ancestry. Some phthisis also in paternal ancestry. One paternal and one maternal uncle had epilepsy.

History of the Case.—Patient was a delicate child and was circumcised when eighteen months old for peevishness, crying, and sleeplessness.

In April, 1881, he had a series of epileptic attacks. The next series followed in October, 1881. Both were very severe and several attacks occurred in succession, chloroform being required to control them. Screaming attacks were frequent at night and would last for hours.

The child was at once put upon bromides and did not have another severe attack for a year, but had numerous attacks of petit mal. A third series of severe convulsions occurred in October, 1894. He was then put on full doses of bromide and corrosive sublimate and had no severe seizure until March,

1887, but during this time had very frequent attacks of petit mal

In 1885, severe outbreaks of uncontrollable temper occurred; the child could not be trusted with children, and in temper had been known to throw knives, forks, or anything he could lay hands on.

From that time petit mal attacks have been very frequent, and he has had a series of severe convulsions in March, 1887, December, 1887, August, 1888, and November, 1888.

He has taken heavy doses of bromides periodically, but they seemed to exert no special influence.

Eye Defects.—Under atropine patient showed: Hypermetropia, O. D. + 0.75; O. S. + 0.50; abduction, 38°; adduction, 6°—; sursumduction—right, 3°; left, 3°; no hyperphoria; esophoria, 6'.

Within a week after wearing esophoria prisms he showed, while wearing a 5° prism: Esophoria, 8°; abduction, 2°—.

Treatment and Results.—On account of the age and peculiar temperament of the child, it was found impossible to operate upon him under cocaine. Not even his nurse, who had great influence over him, could persuade him even to have a solution of cocaine dropped in his eye.

As he showed homonymous diplopia with a red glass and at times as much as 20° of esophoria, it was deemed wise by his attending physician and myself to operate under chloroform. He was put under the anaesthetic with difficulty, and both interni were rather freely divided. Great care was taken to avoid an overcorrection, and, accordingly, the result was not as good as might have been obtained had I followed my customary methods and tested the patient's muscles after each tenotomy.

Two days after the operation the tests showed: Esophoria, 0° to 6°; abduction, 6°.

Three days later the patient had a very severe convulsion, preceded by a long awra of terror. This seizure required the administration of chloroform to control it. It was followed by eleven light attacks.

The child began to develop considerable latent esophoria within the next month, and it was becoming evident to my mind that further operative work on his interni would be demanded.

To my great disappointment, the parents then decided to discontinue treatment for a while at least, as even the thought of further tenotomies seemed to greatly disturb the child and his parents.

Under such circumstances very little, if any, benefits could reasonably be expected from the eye treatment up to this point, as the case was one that would undoubtedly require considerable time for the full solution of the eye problems encountered.

I am informed that subsequently the parents placed the child in a private institution in England.

Case XXV.—Miss C., aged fifteen years. Referred to me on April 7, 1892, by Dr. F. H. Olin, of Southbridge, Mass.

Family History.—Mother is delicate with pulmonary trouble. Maternal grandfather died of phthisis. Father has had severe headaches all his life. His mother and all of his brothers also have headaches. No chorea, epilepsy, or insanity in ancestry so far as known.

History of the Case.—Patient had spasms in infancy, which were attributed to indigestion. About four years ago she began to have light attacks of epilepsy in school. In these she had an "aura" and momentary lapses of consciousness, but never fell.

In August, 1891, she had an attack in a store, walked into the street unconsciously, fell in the street, and was carried back into the store. She was at once put upon bromides, as she showed marked indications of another attack the next day.

In September, 1891, she had her second severe fit in a drug store, and was carried home semi-conscious by her family physician. Bromides were pushed for three months and then were stopped for a month.

Mild attacks appeared in January, 1892, and bromides were again commenced.

In March, 1892, she had her third severe attack, followed by another inside of an hour. Both of these were terribly severe.

At present it is a rare thing for her to go a day without a light attack, and she often has several in a day.

All bromides were stopped a week ago.

In other respects the patient is well and strong. She is a remarkably bright girl and an accomplished musician.

Eye Defects.—Under atropine the patient showed: Hypermetropia (+0.50); adduction, 28°; abduction, 4°+; sursumduction—right, 1°+; left, 1°+; right hyperphoria, 0.25°; esophoria, 1°.

After exercise of the muscles and use of prisms for a week, she showed, while wearing 4° prism: Adduction, 45°; abduction, 1°; no hyperphoria; esophoria, 5°. Later she developed considerable latent esophoria and right hyperphoria.

Treatment and Results.—The treatment of this case consisted in the wearing of prisms and a graduated tenotomy upon the left inferior rectus and both internal recti muscles. The esophoria operations were performed within the first month, about two weeks apart. During the next month her muscles were tested almost daily, and esophoria prisms were given for suspected latent trouble; but, her tests being rather uncertain, the prisms were removed and the patient sent home for the summer. At that time she showed adduction, 50°; abduction, 6°+; no hyperphoria; no esophoria.

During these ten weeks she went several times from one to two weeks without any attacks, and would then have several light ones, usually during menstruation. She had no severe attack during this period of ten weeks.

July 28, 1892.—Her mother reports that during the past five weeks she has had nine slight attacks, four of them during menstruction. In none of these was she unconscious.

September 29th.—Patient returned to-day for further treatment, and reports eight light and no severe attacks for the past two months. Her eye tests were taken daily for a week, but, as no esophoria disclosed itself, she was sent home for six weeks. Her tests were: Adduction, 45°; abduction, 5°+; no hyperphoria; no esophoria.

January 10, 1893.—Since last note (twelve weeks ago) the patient has had five severe and fifteen light attacks.

February 16th.—Patient returned to-day for treatment. She began to show some right hyperphoria, and prisms were given to correct it, and increased in strength as fast as she showed any surplus over her glass. Within ten days she showed: Adduction, 43°; abduction, 4°; sursumduction—right, 4°+; left, 0°; right hyperphoria, 3°; esophoria, 0°.

The left inferior rectus was then divided, and six days after the operation she showed: Adduction, 45°; abduction, 5°; sursumduction—right, 1°+; left, 1°+; right hyperphoria, 0.25°; no esophoria.

Prisms were given her for exercising the externi daily, and she was sent home.

April 19th.—Patient's mother reports that she has had five severe and eleven light attacks in the past nine weeks, and that her abduction is 7°.

In November, 1893, her physician visited my office and reported that this patient "was, in his opinion, decidedly better than when under the influence of bromides." She had few severe fits, longer intervals between them, and a very marked decrease in the petit-mal attacks had been observed.

The correction of the existing het- erophoria in this case is probably imperfect. Fur- ther operative work will doubt- less have to be done before ortho- phoria is estab- lished.

## INFLUENZA (LA GRIPPE).

By EDWIN R. MAXSON, M.D., A.M., LL.D., SYRACUSE, N.Y.

Nature.—This disease, now so prevalent, the result, perhaps, of a poison originally generated by the decomposition of animal and vegetable matters in the inundated regions of China, and intensified possibly by exhalations from the marshes and hovels of squalid poverty in Russia, has had its run around the world.

Whatever may have been the origin of the microbe which causes influenza (la grippe), it now appears to be generated or prevalent the world over, the disease increasing in intensity from year to year, and becoming more generally prevalent and complicated.

The poison, wherever generated, is evidently one of more than ordinary persistence and considerable virulence. For, if not destroyed early in any case, the tendency is to derange, in turn, the various vital and voluntary functions. And though the poison may doubtless be introduced through the respiratory and digestive mucous membranes, in the main, it evidently spends its early influence upon the cerebro-spinal system, and especially the base of the brain, medulla, and cervical spinal cord, from which, as a center, through the cerebro-spinal and ganglionic nerves, the complications in this disease arise.

When the brain more especially suffers, intense pain, delirium, intolerance of light, and mania may follow in quick succession, involving perhaps the eye, but more frequently, as appears, the internal ear of one or both sides, constituting Menière's disease, irritative or destructive.

In cases in which the tonsils become more especially involved, the pain and swelling may be slight, or considerable, if not early controlled.

Perhaps more frequently the thoracic structures, and especially the bronchial mucous membranes, may take on the principal local diseased condition; less frequently the lung tissues, pleura, pericardium, and heart muscle, or endocardium, with a rapid development of the symptoms pertaining to each. When it is the heart muscle which is more especially affected, it may be an exalted or depressed derangement, inflammatory or functional, especially in persons addicted to the use of tobacco, a notoriously frequent cause of heart failure, as is well known.

Gastric inflammation, acute or chronic, appears to be an increasing feature of influenza (la grippe) not early controlled, and may constitute an early condition of a grave character, more especially of late.

Such, then, may constitute the conditions in this disease when fully developed, attended with a coated tongue and the usual symptoms belonging to each, with an utter loss of appetite in all cases, the premonitory symptoms being those of a common cold and a lame neck.

It must be apparent to all acquainted with this disease that decided early treatment is of great importance in order to avoid the complications so liable to arise if not arrested early. And as patients undergoing the premonitory symptoms so generally believe that they have only a "cold coming on," it is well to inquire if they retain an appetite; and, if not, to remind them that a cold rarely or never destroys the appetite.

Then they may be convinced of the necessity of using means to arrest the disease before complications arise.

And, if so, the disease should be arrested, usually within five days, according to my observation in a great number of cases since it has prevailed in this region. But when complications arise from neglect or inefficient treatment more time may be required, depending upon the seat and nature of the complications. But it is my opinion that cases of any age should generally recover under judicious treatment timely administered.

Treatment.—I give to adults two grains (thirteen centigrammes) of sulphocarbolate of sodium every six hours—at six, twelve, six, and twelve o'clock—as an antiseptic, and with it generally two drops (0.06 c. c.) of tincture of nux vomica as a tonic and to aid digestion. Alternating with this—at nine, three, nine, and three o'clock—I give as a tonic to adults two grains (thirteen centigrammes) of cinchonidine, suspended in rain water and sometimes dissolved by an acid, or tincture of chloride of iron, and proportional doses to children, according to the age. And these three drugs are continued during and for several days after all symptoms of the disease have disappeared, to destroy the poison as fast as the spores germinate, for I do not believe the spores (seeds) before germinating can generally be destroyed by safe means.

At the very commencement I give to adults a three-grain improved cathartic pill, less for children, usually at evening, till the tongue becomes clean; and each day, from the first, a warm footbath is directed once or twice, according to the fever developed. Hot toast water with milk only is directed, except at mealtimes, when with toast and, if admissible, egg, hot weak tea is allowed to those accustomed to its use.

For the lameness in the back of the neck, which I have generally found a primary symptom, if of sufficient severity to require attention, a wet or dry cup will usually afford immediate relief, applied high to the back of the neck, relieving also the head if aching, as is often the case, with great severity, attended possibly with delirium or mania.

When there is bronchial or any pulmonary irritation, with a cough, I give every six hours with the cinchonidine to adults five grains (thirty-three centigrammes) of Squibb's chloride of ammonium, dissolved in half an ounce (fifteen cubic centimetres) of syrup or water, proportionally less for children, and continue it while there is any bronchial or pulmonary disease of any kind remaining. Sinapisms, hot, are also used once or twice daily. And when pneumonia, pleurisy, pericarditis, or carditis occurs, cups, wet or dry, are applied over the seat of the inflammation and along the corresponding side of the spine opposite, and repeated if necessary, and followed by blisters if required, over the inflamed part.

In cases in which the structures of the internal ear or of the eye become involved, blisters back of the ears, to the back of the neck, and temples may be required and perhaps repeated.

In gastric complications, if sinapisms fail to subdue the inflammation, cups or blisters may be required.

When amygdalitis is a complication a flannel, folded, should be placed loosely around the neck, and a gargle made by dissolving half an ounce (fifteen grammes) of pedicle.

chloride of ammonium in a pint (480 c. c.) of water, three parts, and vinegar, one part, may be used after each meal and mornings and evenings till the inflammation is subdued.

Later, should the fauces remain irritable, a gargle made by dissolving a teaspoonful each of alum and borax in half a pint (240 c. c.) of sage tea, sweetened, may be substituted and used mornings and evenings while needed.

Having thus subdued the complications and directed a continuance of the antiseptic, nux vomica, and cinchonidine for several days after all the symptoms have subsided, in gradually diminished doses for aged people, it may be well to direct a cold infusion of calumba root, in tablespoonful doses, before meals, till the appetite is fully recovered.

818 Madison Street.

## REPORT OF TEN CASES OF SUPRAVAGINAL HYSTERECTOMY FOR FIBROIDS OF THE UTERUS.

By CHARLES S. HAMILTON, A. B., M. D., columbus, ohio,

The writer wishes to report all of his cases of supravaginal hysterectomy for fibroids. It will be seen from the tabulated statement that the tumors varied in size from fifteen pounds downward. All the patients recovered from the operation. One (in Case II) died of organic heart disease four months later.

Nothing has been learned of the patient in Case I since her discharge from the hospital. The appendages were removed when seriously diseased or when their ablation greatly simplified the operation. In young subjects with sound appendages a tube and ovary were left to minimize the disturbance of the nervous system. In women approaching the climacteric, or having already entered upon it, the treatment of these organs was determined by their relation to the growth and the diseased appearances that they manifested. The stump was secured extraperitoneally with elastic ligature and fixation pins, after tying the whole or a portion of the broad ligaments. The constrictor was carried both above and below the pins to prevent its slipping either up or down on the pedicle. In the first cases the peritonæum was stitched around the stump. This line of sutures is deeply located, sometimes difficult to insert, and may become septic from the stump and lead to infection of intra-abdominal ligatures. If this happens, a persistent sinus results. Therefore in several of the more recent operations the peritonæum was carefully coaptated to the uterine structure without sutures with satisfactory results.

When the tumor had been cut away a saturated solution of chloride of zinc, pure carbolic acid, or the cautery was applied to the pedicle and exposed cervical mucous membrane. Gauze was then placed about it in order to isolate it from the abdominal wound. Ordinarily the tissue included by the elastic ligature separated or was ready to be removed with scissors on the tenth day.

In only one case was there any suppuration about the pedicle.

Convalescence was comparatively uneventful and pain- ing table. In one instance repeated curettings and packing less in all the cases, with the exception of Case VIII, in of the endometrium with iodoform gauze might have rewhich there was an attack of peritonitis. The indications lieved the patient in a measure, but, having suffered long, for operation are sufficiently set forth in the accompany- she preferred hysterectomy with sure relief.

## VARIETIES OF SYMPTOMS IN HYPERMETROPIA, WITH AND WITHOUT ASTIGMATISM.

EXAMINATIONS UNDER MYDRIASIS.

BY MARY E. HENNESSY, M. D.

Case I. High Degrees of Hypermetropia and Hypermetropic Astigmatism, mostly Latent .- Emma R., aged twenty-five years, a delicate, tuberculous subject, was sent to the Manhattan Eye and Ear Hospital to consult Dr. Webster October 25, 1893. She complained of: 1. Indistinct vision. 2. Constant frontal headache. 3. Tired eyes. 4. Being obliged to hold the page inconveniently near the face in order to read print.

There was no conjunctival congestion, the brow was without furrows, and the palpebral fissures were very wide, giving the eyes a staring expression. The ophthalmoscope showed transparent media and normal fundi. Refraction, 6:50 dioptres, hyperopic in the vertical, and three dioptres in the horizontal meridian.

Javal's ophthalmometer showed 4.50 dioptres of astigmatism with the rule-i. e., axis 90° or 180°, each eye.

Examination of the extrinsic ocular muscles proved them to be in normal condition-i. e.: 1. Orthophoria, 2, Adduction, 14°. 3. Abduction, 8°. 4. Sursumduction-R., 2°; L., 2°. Vision =  $\frac{20}{100}$ , each eye, without a glass. Vision =  $\frac{20}{70}$ with + 2.75 D. cyl. axis 90°, each eye. In addition to this cylindrical glass she accepted + 1.25 D., each eye, but vision was not improved by it. In this case almost the whole amount of the hypermetropia was concealed or latent. The mechanism of accommodation was thoroughly paralyzed by instillations of sulphate of atropine, and three days later, October 28th, examination with the test glasses gave the following result:

Vision =  $\frac{10}{200}$ :  $\frac{20}{50}$  + with + 6 D. combined with +4.50 D. cyl. axis 90°, each eye.

While the mydriatic controlled accommodation, the following glasses were ordered to be put on at once and worn constantly: + 4 D. \( + 4 D. cyl. axis 90\).

Thus the glasses selected for her corrected two thirds of the total hypermetropia, and all but half a dioptre of the total amount of astigmatism. As the effects of the mydriatic wore away, the eyes gradually became accustomed to the high degree of correcting glasses.

She was requested to return in ten days, which she did, November 8th. Vision was then 20 + with her glasses, and she read Jaeger No. 1, which is the smallest test type, at from eight to sixteen inches with ease. She was asked to return again in a month, and was then found to have improved since her last visit. Vision =  $\frac{20}{30}$  + with her glasses. All her asthenopic symptoms had disappeared. Her countenance was expressive of brightness and contentment; she declared her health had greatly improved. She felt that her education had but just begun. Her glasses continue to give satisfaction, and it may be reasonably expected that her acuity of vision will be considerably increased in course of time.

The foregoing case, with so many asthenopic symptoms, presents a marked contrast with

Case II. Hypermetropia for the most part Manifest.—Aaron S., aged twenty-one years, was sent to me by his employer in July. 1893, with the request that I would "attend to his eyes for near-sightedness." He presented a smiling face, with clear, bright-looking eyes. To my question as to how he complained he cheerfully replied: "Why, I do not complain at all! My eyes give me no trouble; I never had a pain in my eyes or head in all my life. It is true that I am near sighted, but I have tried near-sighted glasses, and I can see better without them. I wish I might be excused from having my eyes examined, but my boss is so kind I suppose I must."

It was very reluctantly that he submitted to the examination, which revealed the following: Vision =  $\frac{2}{2} \frac{9}{0}$ , each eye. He read Jaeger No. 3 at three inches and a half. There was no astignatism. The usual test for the muscles showed them to be in perfect equilibrium. The ophthalmoscope showed ten dioptres of hypermetropia. Vision was brought up from  $\frac{2}{2} \frac{9}{0}$  + with + 6.50 D., each eye. With these glasses he also read Jaeger No. 1 at from seven to eighteen inches.

If we could have used atropine in this case, and allowed him to recover from the effects while wearing his glasses, we could have given him a stronger correction; as it was, he could receive only the amount for the manifest hypermetropia, +6.50 D. being the strongest glasses with which he could obtain distinct vision. They were ordered for constant use, and the patient was requested to return occasionally to report his condition. He came to me in November, 1893. His vision then was \$20 - \text{with his glasses;}\$ and, as he was comfortable and his employer reported him much more useful, industrious, and ambitious than formerly, it was not necessary to change the glasses, and he will continue wearing them unless a change should be indicated later. He was as enthusiastic in his praise of the improved condition of his eyes as he had before been unwilling to have anything done.

Case III. A Small Amount of Hypermetropia that gave a Large Amount of Disturbance; Correction by Glasses.—Ned H., aged thirteen, a healthy, robust schoolboy, was brought to me by his father in July, 1893. He complained so much of headache that had resisted all kinds of medication that the parents had begun to fear his brain was unhealthy.

One physician questioned him as to the locality of the pain, and elicited the facts that it was always confined to the forehead, was most severe over the brows, and grew worse in the afternoon of each day. The doctor correctly pronounced it due to eye-strain, and advised the parents to have a careful examination of the eyes.

When he came to me I found the conjunctive congested, and tears gathered in the eyes whenever he looked steadily at any object. The ophthalmoscope showed a normal condition of the media and fundi. Refraction about  $\frac{1}{2}$  D. hypermetropia; no astigmatism. The eyes were alike in every particular. Vision =  $\frac{a}{12} + \frac{1}{2} + \frac{1}{2}$  he accepted no glass.

Spasm of accommodation being suspected, the boy's eyes were put under the relaxing effects of atropine, and at the end of a week the examination was repeated. Vision  $=\frac{20}{20}+:\frac{20}{10}$  with +0.75 D., each eye.

His total hypermetropia was therefore less than one dioptre; yet this proved sufficient to demand relief, because he was a "lover of books." This triding amount of hyperopia produced fatigue in eyes used so much for near work.

He was ordered what he accepted after atropine had ceased to paralyze the accommodation, that being in this case + 0.50 D., each eye, for constant use. As the patient lived out of town some ninety miles, his father was requested to write of the lad's condition in a month. The report was: "Ned says the glasses tire his eyes."

He was then advised to wear them only for reading and studying till I saw him again, which was three months later. He was much improved, but still had some headache when not wearing glasses, and found that he could read without fatigue or headache with his glasses. He had grown used to the glasses. He was ordered to wear them constantly till the following summer vacation, when he will probably be able to leave them off. I saw the boy after he had worn them constantly for three months and found that he had had in that time neither headache nor tired eyes. No asthenopic symptom remained; he was made comfortable by this correction.

CASE IV.—Hypermetropia producing Blepharitis Marginalis as the Only Symptom.—Mabel T., aged eleven years, a schoolmate of the patient in Case III, was brought to me at the same time by the advice of the same physician. She was a delicate girl, whose parents had both died of phthisis. She had had "red eyelids since she commenced going to school," was the history given by her aunt. No other symptom could be discovered. The margins of both upper and lower lids were red, thickened, and covered with yellow crusts. The child was sometimes avoided by other children because of the appearance of her eyes. R. vision =  $\frac{9}{10} + \frac{9}{10} + \frac{9}{10} = \frac{9}{10} - \frac{9}{10} = \frac{9}{10}$ 

The ophthalmoscope showed a normal condition of the media and fundi. Refraction of the right eye, + 1·25 D.; of the left eye, + 1·50 D. No astigmatism. Accommodation being overcome by atropine, vision = R.,  $\frac{20}{30}$ :  $\frac{20}{10}$  — w. + 1·25 D. L.,  $\frac{20}{30}$  — :  $\frac{20}{10}$  — w. + 1·50 D.

The following correcting glasses were ordered to be put on while the atropine controlled accommodation, and worn constantly: Right eye, + 0.75 D.; left eye, + 1 D. The lids were bathed with borax water (3 j to Oj) till the scaly crusts were removed, after which the following ointment was used every night and morning for two weeks: B Powdered yellow oxide of mercury, gr. xvj; vaseline, 3 j.

She wore these glasses with comfort, and the inflammation of the margins of the lids entirely disappeared, and they remained well for four months, when they again became somewhat reddened. As a return of the objectionable condition was feared, the child was promptly brought to me for advice. This was in November, 1893. I found she then accepted, in addition to the glasses she was wearing, \( \frac{1}{4} \) D., each eye. I then ordered for the right eye + 1 D., for the left + 125 D. No treatment of the lids was employed. After she had worn the stronger glasses a week the redness disappeared, and now, at the end of four months, the lids continue in a healthy condition

CASE V. Only One Third of the Total Hypermetropia Manifest; Multiplicity of Subjective Symptoms.—Mrs. E. E., aged twenty-nine years, a healthy, strong woman, came to me in January, 1894, declaring that she "must have some dreadful disease of the eyes." She complained of: 1. Very indistinct vision. 2. Being unable to read by gaslight. 3. Frontal headache and pain in the eyeballs. 4. Mental confusion upon trying to distinguish objects. 5. Insomnia, that she was certain was caused by the condition of her eyes.

She had always had poor vision; she remembers that when she was a little child at school she had difficulty in distinguishing characters upon the blackboard, and in reading, the letteraoften ran together, and she would frequently stop at that time and rub her eyes, finding that gave some relief and for a brief time enabled her to see print more clearly.

In the early part of December, 1893, she had an attack of

influenza, and since that time her vision and her headaches have been decidedly worse. She was extremely nervous.

Right, vision =  $\frac{20}{100}$ :  $\frac{20}{50}$  - w + 2 D, combined with + 0.75 D, cyl. axis 90°. Left, vision =  $\frac{20}{50}$ :  $\frac{20}{50}$  w, + 2 D.

The ophthalmoscope showed a normal condition of the media and fundi. Refraction: Right eye, + 6 D., with + 1 D. astigmatism; left eye, + 6 D.

Examination of the Ocular Muscles.—1. Hyperphoria, R. 1.5°. 2. Esophoria, 2°. 3. Adduction, 16°. 4. Abduction, 6°. 5. Sursumduction—R. 2.5°, L. 1°.

This patient's eyes were put under the controlling effect of atropine, and three days later the following result was obtained:

R. V. =  $\frac{2}{3}\frac{6}{6}$ ;  $\frac{2}{3}\frac{6}{6}$  + with + 6.50 D. combined with + 1.25 D. cyl. axis 60°. L. V. =  $\frac{6}{2}\frac{6}{6}$ ;  $\frac{2}{3}\frac{6}{6}$  + with + 6.50 D.

Before accommodation was restored the following glasses were ordered for constant use: R., +4.50 D.  $\bigcirc +1.25$  D. cyl. axis 90°. L., +4.50 D.

After the mydriatic had ceased its effects vision was found to be: R. =  $\frac{2}{70}$ , without a glass. L. =  $\frac{2}{70}$ , without a glass. Each eye, with a glass, =  $\frac{2}{30}$  +. The two eyes together, with glasses, =  $\frac{20}{13}$ . With these glasses she read Jaeger No. 1 at from seven to eighteen inches. Without her glasses she could read only Jaeger No. 3, and with pain and difficulty.

She was requested to return in a month to report her condition

In February, 1894, she returned and stated that all her asthenopic symptoms had disappeared. All objects, whether near or distant, were plainly seen. Her glasses continue to give her satisfaction and comfort. She even slept well, whether she read in the evening or did not use her eyes for near work.

This patient had all her life suffered from this high degree of hypermetropia, and this was her first sense of relief. She presented a marked contrast to the patient in Case II, and in some respects to the one in Case I. Her forehead was deeply furrowed with vertical lines between the brows, the palpebral fissures were contracted, and she had an anxious, troubled countenance, as if uncertain what to do. All this facial expression changed as her other asthenopic symptoms disappeared under the proper correcting glasses.

Case VI. Two Thirds of the Total Hypermetropia Manifest; Distressing Asthenopia.—Ida W., aged twenty-five years, a delicate, overworked young woman, was sent to me on January 3, 1894, by a philanthropist, whose special interest is in working girls. The patient was employed in the "stamping of linen," an occupation demanding close application of the eyes for many hours a day—an "asthenopic occupation," as Dr. Roosa calls such work—i.e., "an occupation which will produce asthenopic symptoms in eyes that would otherwise probably not be complained of."

She gave the following history: At the age of twelve years she had an attack of spinal meningitis; was ill then nine weeks, being delirious the greater part of that time, and made a slow recovery. Since that time she has always suffered from severe headache, at times being quite overcome by the pain and obliged to go to bed. This was regarded, both by the physician who attended her and by her own family, as the result of her serious illness before mentioned. When she came to me her subjective symptoms were as follows:

- 1. Constant hendache, which was always worse in the after-
- 2. Indistinct vision for distant objects.
- The necessity of holding her head low to see lines at her work upon the table.
  - 4. Nervousness.
  - 5. Tired and painful eyeballs.
  - 6. Drowsiness.

The eyelids drooped, and her facial expression was sad and dull, though her conversation was good. She looked drowsy, and seemed to require encouragement even to complain.

Vision =  $\frac{2.0}{10.0}$  +:  $\frac{2.0}{2.0}$  — with + 4 D., each eye. The ophthal-moscope showed normal media and fundi. Refraction, + 6.50 D., each eye. No astigmatism. Muscles in equilibrium. As this patient could not afford time for a more thorough examination under atropine, she was given the strongest concave glasses with which she could procure distinct vision, thus correcting only her manifest hypermetropia, which was, as above recorded, + 4 D., each eye.

She was ordered these for constant use, and will be expected to accept a stronger correction in the course of a few months, as she gradually relaxes accommodation under this correction. As soon as the glasses were put on she experienced a sense of "rest," as she called it. She returned in three weeks, on February 1st, and the change in her expression and manner was quite noticeable. Her eyes were "open" instead of half closed, her face had lost the sad, dull look, and her manner was confident and cheerful. She stated that her headaches had disappeared, and that she was no longer drowsy, even though often up late at night.

Her vision was then  $\frac{20}{15}$  with her glasses, and she read Jaeger No. 1 at from eight to twenty inches. Her own statement was: "I seem to have gotten out of a gloom that covered everything before."

This patient was certain that her defective vision had produced drowsiness, as in Case IV the patient was convinced that her defective eyes were answerable for her insomnia. However, the fact remains that both the one and the other were completely relieved of these conditions after their refraction was corrected. Each had about the same degree of hyperopia. Their several occupations, individual temperaments, past condition of health, etc., were factors not to be ignored in attempting to arrive at a conclusion as to the exact part this error of refraction played in the production of insomnia in the one and the very opposite condition in the other.

17 East Thirty-first Street,

#### ALCOHOL: ITS USE AND ABUSE.

BY WALTER SANDS MILLS, M.D., STAMFORD, CONN.

Alcohol may be a food, a medicine, or a poison. The physiological action of alcohol is a much-mooted question. At first sight it would seem odd that no two authorities should agree on the action of a drug so generally in use. But the difference of opinion is due, partly, to that very fact, for the action of the drug is very different on those accustomed to its use and on those unaccustomed to it; another reason for this difference of opinion is that no two investigators have gone to work in the same way. Until accurate scientific experiments, similar in every detail and conducted by different observers, so that comparison of results may be made, each student will have to draw his own deductions from the evidence at his disposal and from his own observations, and his opinion will vary accordingly.

A small quantity of alcohol acts on the cerebro-spinal

system, giving a sensation of warmth by causing a relaxation of the terminal capillaries and a consequent flush of blood to the body surface. There is no actual rise in temperature; the flush of external heat is at the expense of the internal organs. Large doses of alcohol cause an actual lowering of the temperature. The cardiac force and arterial pressure are increased by the physiological dose. The functional activity of the brain is augmented. There is a feeling of mental and physical exhilaration, followed by one of comfort and repose. If the ingestion of alcohol is continued to toxic doses, this disturbance of the system becomes more and more marked; the exhilaration is changed to intoxication; there is loss of co-ordination, loss of muscular power; the subject sees everything double; there is sleeplessness, delirium, anæsthesia, and, when the full limit is reached, collapse. The picture is not a pleasant one. Alcohol is a true poison, and a person who has taken a full toxic dose is in an alarming condition. The temperature is subnormal; the body is bathed in a cold perspiration; the pulse may be so weak as not to be felt, it may be very slow or very fast; the breathing is labored and stertorous; the pupils may be contracted or dilated, they do not react to light; the lips are blue, the insensibility is profound. This condition may terminate in recovery or in death.

A period of reaction invariably follows the excitant stage of alcohol. The greater the quantity ingested, the more prompt and the greater the following depression. One ounce of alcohol, diluted, taken during the twenty-four hours and always after meals, is considered the limit of physiological usefulness. More than that quantity will in time produce pathological results. From the nature of its reaction it is self-evident that alcoholic stimulation is not a good thing to do work on. It has been proved time and time again that continuous work, either mental or physical, is only made harder by using alcohol as a stimulant. The vital powers are assisted for a short time, to be left in a more exhausted condition after the temporary effect has worn off.

Alcohol lessens the power of enduring severe heat or severe cold. The experience of arctic explorers has been universal in that man's ability to withstand the extreme cold of Northern latitudes is lessened by the taking of alcohol.

After a severe mental or physical strain, when the vitality is exhausted, a small quantity of alcohol as a restorative and sedative may be of service; but it is never of use as a stimulant to continue working on.

Some of the alcohol taken into the system is assimilated; it is therefore a food. Some of it is given off unchanged by the organs of elimination. It is found in the breath, in the perspiration, in the urine, in the fæces. It has also been found, unchanged, in nearly all the organs and tissues of the body, particularly in the nervous system and in the liver.

The amount of urea eliminated is decreased. The amount of urine is increased.

Alcohol taken into the stomach, diluted, and in small to adquantities, assists digestion by stimulating the mouths of ment.

the gastric glands and causing an increase in the flow of the various juices. If the use of alcohol is habitual, we eventually have a catarrhal condition due to overstimulation with consequent faulty digestion. Alcohol in quantity precipitates pepsin and impairs its utility, giving another source of alcoholic dyspepsia.

Alcohol passes rapidly from the stomach into the por tal circulation. Here it stimulates the hepatic cells, and in time causes fatty and atrophic changes, with an increase in the connective tissue.

This impairment of the parenchyma of an organ, with an increase of its connective tissue, is one of the results of the habitual use of alcohol generally throughout the economy. Post-mortem changes of this nature are readily observed in habitual drinkers.

Absence of Genitalia. — Kochenburger (Zeitschr. f. Geburtsh. u. Gynäk.; Arch. of Gynacol., Obstetries, and Padiatrics, December, 1893) describes this case. The patient was distinctly feminine in general development. The mamma and mons Veneris were well developed. There was a slight fold in the vestibule, which was shallow, and no fossa between the labia minora. No vagina existed. In its place lay a cordlike structure which ran upward an inch and a half and ended in a fold which ran transversely and clearly represented Müller's ducts; no trace of an ovary could be found. Vicarious menstruation, in the form of epistaxis, occurred regularly.

The Lyman Prize.—The Lyman prize established for graduates of the Boston City Hospital, of not more than three years' standing, by Mrs. George H. Lyman, in memory of her husband, Dr. George Hinckley Lyman, who was a member of the medical staff of the hospital for many years, has been awarded this year, in two equal parts of one hundred and fifty dollars each, to Dr. John Lovett Morse, of Boston, for an essay entitled A Bacteriological Study of Four Hundred Cases of Inflammation of the Throat in Diphtheria and Scarlet Fever, with Special Reference to Pathogenesis, and to Dr. Arthur Howard Wentworth, of Boston, for an essay entitled A Study of the Blood in Early Life. The usual prize is one hundred and fifty dollars, but no prize was awarded last year.—Boston Medical and Surgical Journal.

The West End Medical Society.—At the annual meeting, held on February 3d, the following officers were elected for the ensuing year: Dr. F. Spencer Halsey, president; Dr. S. V. Ten Eyck, vice president; Dr. F. J. Blodgett, recording secretary; Dr. H. G. Meyers, treasurer; Dr. H. S. Houghton, corresponding secretary; and Dr. C. B. White, pathologist.

The Rinecker Prize of the University of Würzburg for this year, amounting to a thousand marks and a silver medal, says the *Deutsche Medizinal Zeitung*, has been awarded to Professor Camillo Golgi, of Pavia, for his researches in neurology.

The French Academy of Medicine.—The Progrès médical announces that Dr. Laveran has been elected a titular member, to fill the vacancy in the Section in Therapeutics and Medical Natural History caused by the death of Dr. Marotte.

The Central University, of Kentucky.—On the 9th of January a new building for the Hospital College of Medicine and the Louisville College of Dentistry, which are departments of the university, was dedicated in Louisville.

The Kentucky School of Medicine, of Louisville, is about to add a handsome and capacious new building to its equipment. THE

NEW YORK, SATURDAY, FEBRUARY 17, 1894.

#### INTERMITTENT NEPHRYDROSIS.

AT a recent meeting of the Paris Société de chirurgie, a report of the proceedings of which we find in the January number of the Revue de chirurgie, M. Tuffier remarked that three points had to be studied in the consideration of intermittent nephrydrosis-namely, the ætiology and pathogeny, the pathological anatomy, and the treatment. It seemed to him certain that the affection was almost always directly connected with a movable kidney. Facts sustained this, for it was almost invariably met with in women and nearly always affected the right kidney. The mechanism was that which had been maintained by Landau. M. Tuffier had come to a realization of it experimentally. In eight dogs he had rendered the kidney movable, and had then fixed it in an abnormal situation; in four instances nephrydrosis had been the result, and this proportion was about the same as was observed clinically. This nephrydrosis was accompanied by the formation of a sharp bend in the ureter at the point where it crossed the vessels, about two thirds of an inch below the hilum of the kidney. Simple compression of the kidney was sufficient to cause the urine to overcome the impediment offered by this bend. The bend could be straightened out, and the nephrydrosis would then disappear at once. Anatomical facts observed in the course of operations also spoke in favor of the same mechanism. In two patients the speaker had distinctly observed the bend in the course of an operation, and in a third patient he had observed at a point about an inch below the hilum a sudden change of caliber in the ureter, indicating that there had been a folding at that point. This bend could be made to disappear by a change in the attitude of the person; one of the attachés of the Hôpital Beaujon, who had a movable kidney, perceived that her flank increased in volume and became painful when she remained standing, but that as soon as she lay down and raised her hips decidedly the swelling disappeared and she felt herself relieved and passed water copiously.

Experiments showed, the speaker went on to say, that when the kidney was lowered, at first there was formed, not a sharp bend, but a curvature, and this curvature was sufficient to diminish the flow of urine. At the same time intense renal congestion took place, and the kidney underwent a change of shape. Two types of such change were met with: sometimes the organ took the form of a horseshoe, at other times it was flattened. As for the phenomenon of intermittence, there were two ways in which it could be explained: The bend might be straightened out spontaneously by virtue of the mobility of the kidney; in other cases the tension of the kidney might overcome the impediment and result in the expulsion of the urine.

Of the methods of treatment that had been proposed, preference should be given to the operation of fixation of the kidney. The author had practiced this in nine cases, and in all of them success had been the result.

#### THE KNEE-JERK IN CASES OF CYANOSIS.

In the Lancet for January 20th we find one of an interesting series of communications by Dr. J. Hughlings Jackson which he styles Neurological Fragments. In this particular communication he states that he has not recently had opportunities of making observations with regard to the state of the knee-jerks in many cases of excessively defective oxygenation of the blood. He gives summaries, however, of three cases observed by Dr. Hawkes, a former house physician of his at the London Hospital. One case was that of a boy, six years old, who died of broncho-pneumonia. On the morning of the day before his death the patient's knee-jerks were present, in the evening of that day they were not elicited with certainty, and on the next morning they could not be elicited. This case, Dr. Jackson remarks, is not of much value as to the influence of defective oxygenation of the blood, for the jerks were absent only on the day of death.

The second case was that of a woman, fifty years old, who was admitted on the 19th of April, 1893, at 6 P. M., unconscious and cyanosed. She had taken laudanum, which she had been in the habit of taking for dysentery. It was supposed that she had taken two ounces. Her knee-jerks were absent. At 6.45 P. M. the pulse was 132 and stronger; the respiration was 4, expiration being very prolonged; the knee-jerks were absent; there was no corneal reflex; and the pupils were of about the size of a pin's point. In spite of the administration of oxygen, the knee-jerks remained absent until 11 P. M. and possibly longer. At 2 A. M. on the 20th consciousness was returning, and at 2.45 the patient answered questions. On her recovery, the knee-jerks were elicited. Dr. Jackson says that he can not be certain that absence of the knee-jerks in this case was due solely to defective oxygenation of the blood; for aught he knows, opium itself in poisonous doses may abolish them. The knee-jerks were absent before the subcutaneous injection of a quarter of a grain of atropine at 6.45 P. M. on the 19th.

The third case was that of a man, fifty-four years old, who was admitted into the hospital at 12.50 a.m. on February 7, 1893, after having taken an ounce of chlorodyne. He was not altogether comatose, and resisted the introduction of the stomach-tube; but at 1.15 r.m. he was quite comatose, and the faradaic current did not rouse him in the least. He recovered. His knee-jerks were present throughout.

Dr. Jackson thinks it desirable that the knees should be tested in cases of cyanosis from whatever cause. It is to be borne in mind particularly that, according to Dr. Russell's researches, in asphyxiated dogs and rabbits the knee-jerks are exaggerated before they are lost, and after they return they become exaggerated again before they become normal. In most cases of asphyxia from disease in man defective oxygenation of

the blood develops slowly and increases gradually; in dogs that are asphyxiated artificially it begins saddenly and attains its maximum rapidly.

#### MINOR PARAGRAPHS.

THE PROPOSED NATIONAL BUREAU OF PUBLIC HEALTH.

Appropos of the leading article in the Journal for January 27th, in regard to the supererogatory and futile features of a bill before Congress proposing to establish a bureau of public health, we would refer to the action of the Memphis Medical Society in regard to this bill. The Memphis Medical Monthly for February states that the bill was submitted to a committee of the society for consideration. Among the members of this committee were R. W. Mitchell, one of the most distinguished sanitarians in the Mississippi Valley, who was a member of the late National Board of Health from its origin until it went out of existence; Dr. G. B. Thornton, whose administration of the office of president and executive of the Memphis Board of Health has made that city's sanitary condition what it is today; Dr. J. E. Black, an ex president of the Memphis Board of Health and an ex-official of the National Board of Health; and Dr. F. L. Sim, a member of the Tennessee State Board of Health. We cite the names and qualifications of these gentlemen in order to show their competency to speak in regard to the question at issue. The committee stated that, after examining the full text of the contemplated law bearing on national quarantine, it did not see wherein it was better than the law of January 13, 1893. The latter was full and comprehensive in theory, and, so far as it had been tried, was effective in practice; and the passage of the proposed law would supersede, or so interfere with, that law as to be undesirable and unwise. Hence the committee reported adversely to any action on the part of the society calculated to interfere with the status of the national maritime and inter-State quarantine law now in force. The report was adopted by the society. We believe that this action, based on an expression of opinion from experienced and practical rather than theoretical sanitarians, and substantiating all that was said in our article in regard to the objections to the enactment of any such law, will receive the indorsement of the majority of actual sanitarians in this country, if not of all of them.

## PULMONARY CONSUMPTION AND BOARDS OF HEALTH.

In this issue we print nearly the whole of the discussion that took place at a recent special meeting of the College of Physicians of Philadelphia, called to consider a resolution affirming it to be the sense of the college that it was inexpedient for the board of health of that city to require reports of the occurrence of tubercular disease and to treat the quarters occupied by the victims of such disease by means of disinfection, etc. We do not regret devoting so much space to this discussion, for several of the most distinguished physicians of Philadelphia took part in it, and what they said is replete with interest to all our readers. It is evident that there is a good deal to be said on either side of the question, but we must conclude that the College of Physicians was wise in adopting a resolution calculated to discourage undue zeal on the part of the board of health. Whatever theoretical views we may hold, and however perfectly those views may seem to be borne out by facts, it must be recognized that the stamping out of pulmonary consumption, or its decided reduction, by official action is fraught with practical difficulties that make it almost impossible. Still, the attempts of boards of health to do something toward accomplishing this object are certainly commendable, and we

may add that cautious and tentative steps in the line of their enforcement may even achieve considerable good while doing little if any injury to individuals. The question is one that can not yet be looked upon as having been worked out to a satisfactory solution.

#### CHRONIC PAROTIDITIS.

In the Journal des praticiens for January 20th there is a report of a meeting of the Société médicale des hôpitaux at which Dr. A. Renault showed a woman, forty-one years old, who had entered the Broca Hospital in December. She had been attacked with an inflammatory affection of the throat four years before, and following that attack there had been a purulent discharge. Some time afterward she had been subjected to antisyphilitic treatment, and since that time the parotid glands had remained painful and swollen. At the present time they were hypertrophied and sensitive to pressure. There was no lesion of the mouth, and Stenson's ducts were permeable. Sometimes she discharged saliva in great quantity, and gentle pressure on the glands was sufficient to make the saliva flow. The case was considered to be one of chronic parotiditis. M. Anthony remarked that he had observed chronic parotiditis in a man who had had mumps, but in that case there had been no salivation.

#### THE LATE BISHOP POLK.

The London house of Longmans, Green, & Co. has just published a book entitled Leonidas Polk, Bishop and General, written by the second and only surviving son, Dr. William M. Polk, of that conspicuous figure of our late conflict. The work is issued in two handsome volumes, with four steel plates and nine maps. It is stated that it contains much of original, or hitherto unpublished, records and correspondence of the soldier-bishop. The style of composition is of the direct, unvarnished variety that befits a busy practitioner who assumes the cares of authorship.

### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 13, 1894:

DISEASES.	Week end	ing Feb. 6.	Week ending Feb. 13.		
Diodiadoo	Cases.	Deaths.	Cases.	Deaths.	
Typhus	0	0	0	0	
Typhoid fever		2	1	0	
Scarlet fever	147	18	141	18	
Cerebro-spinal meningitis	()	0	2	2	
Measles	586	32	573	24	
Diphtheria	192	73	178	57	
Small-pox		8	24	10	

The Columbia Chemical Company.—We are requested to announce that Dr. William A. Hammond, having demonstrated his right to hold stock in a manufacturing company, has disposed of his entire interest in the company, with which he has no further connection.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 28 to February 10, 1894:

SMITH, JOSEPH R., and IRWIN, BERNARD J. D., Colonels and Assistant Surgeons General, are detailed to represent the Medical Department of the Army at the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894, and will proceed to the place designated at the proper time.

Town, Francis L., Lieutenant Colonel and Deputy Surgeon General, is relieved from duty at Fort Porter, New York, to take effect on the expiration of his present sick leave of absence, and will report in person to the commanding general, Department of the Missouri, for temporary duty in the office of the medical director of that department.

ROBERTSON, REUBEN L., Captain and Assistant Surgeon, is granted leave of absence for one month, with permission to apply for an extension of one month.

O'RELLY, ROBERT M., Major and Surgeon, is granted leave of absence for two months, with permission to go beyond the sea.

Brooke, Benjamin, First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Leavenworth, Kansas, to take effect upon the arrival of Wilson, William H., First Lieutenant and Assistant Surgeon, at that post, and ordered to Camp Pilot Butte, Wyoming, for duty.

The following-named officers of the Medical Department are relieved from duty in this city (Washington), to take effect upon the completion of the present course of instruction at the Army Medical School, and are assigned to duty at the stations hereinafter designated:

QUINTON, WILLIAM W., First Lieutenant and Assistant Surgeon, Fort Riley, Kansas.

Bratton, Thomas S., First Lieutenant and Assistant Surgeon, Fort Niobrara, Nebraska.

Howard, Deane C., First Lieutenant and Assistant Surgeon, Fort Buford, North Dakota.

PORTER, ALEXANDER S., First Lieutenant and Assistant Surgeon, Fort Keogh, Montana.

WILSON, WILLIAM H., First Lieutenant and Assistant Surgeon, Fort Leavenworth, Kansas.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending February 10, 1894.

STREETS, T. H., Surgeon. Detached from the U. S. Steamer Bennington and ordered to the U. S. Steamer Detroit.

Hibbett, C. T., Surgeon. Detached from the U. S. Steamer Detroit and ordered to the U. S. Steamer Bennington.

Ross, J. W., Surgeon. Ordered to the U. S. Receiving-ship Independence.

Olcott, F. W., Passed Assistant Surgeon. Ordered to the Naval Hospital, Brooklyn, N. Y.

Spratling, L. W., Passed Assistant Surgeon. Detached from the Naval Hospital, New York, and to wait orders.

COOK, FRANK C., Assistant Surgeon. Ordered to the Naval Laboratory and Department of Instruction, New York.

#### Society Meetings for the Coming Week:

MONDAY, February 19th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesday, February 20th: New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Ogdensburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Kings and Westchester (White Plains), N. Y.; Baltimore Academy of Medicine.

Wednesday, February 21st: New York Academy of Medicine (Section in Public Health and Hygiene); the Alumni of Bellevue Hospital Medical College (annual—Carnegie Laboratory); Harlem Medical Association of the City of New York; Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

THURSDAY, February 22d: New York Academy of Medicine (Section in Obstetrics and Gynaecology); New York Orthopedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

FRIDAY, February 23d: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, February 24th: New York Medical and Surgical Society (private).

## Metters to the Editor.

CONCERNING THE FINANCES OF THE ACADEMY OF MEDICINE AND THE ACTION OF THE TRUSTEES.

New York, January 25, 1894.

To the Editor of the New York Medical Journal:

Sir: The editorial on the Finances of the Academy of Medicine, in your issue of January 6th, was brought to the notice of the trustees of the New York Academy of Medicine at their monthly meeting on January 25th. As the article is likely to give rise to misapprehension, the undersigned, the board of trustees, are of the unanimous opinion that you should be requested to publish a refutation of some grave charges contained therein.

Your informant states that the publication of the report of the treasurer of the Academy of Medicine was not accomplished "without the vigorous opposition of some of the trustees, who are said to have taken the remarkable position that the fellows of the Academy should continue in ignorance regarding its financial status. Many of the fellows have desired a more detailed statement, but nobody has seemed willing to take the initiative toward requiring the trustees to print it. In fact, we have heard it stated that some of these officers seemed to think that the Academy was to submit to their dictation, rather than they execute the will of the Academy. But the president, Dr. Roosa, urged that the fellows be made acquainted with the value of their property, as well as with some of its needs, and the majority of the trustees have concurred in this sensible position and have published this report."

The undersigned, while declining to notice the gratuitous insinuation of "dictation," have the pleasure of being able to assure you, and through you the profession, that there is not and never was a difference of opinion on important points between the trustees and the president of the Academy; that the fellows of the Academy were never kept in ignorance regarding its finances; that a detailed report of the same was publiely read at every annual meeting of the Academy; that the report, it is true, was not printed for every fellow and sent to his residence, because such publication and transmission, after the report had been the subject of a public communication, was, in former years, considered unnecessary and uselessly expensive; that, however, when the suggestion was made at a meeting of the board of trustees that the report might be printed and sent to the individual members of the Academy, there was no objection, no unwillingness, no opposition, no discussion at all, but an instantaneous unanimous concurrence.

The undersigned trustees claim, and the medical profession has a right to expect, that the affairs of the Academy shall not be made the subject of unfounded reports. There is no ground

either for suspicion or for concealment. The New York Academy of Medicine is in a flourishing condition, and its officers are all working harmoniously together for the furtherance of its prosperity. It is practically out of debt; the library and its funds are increasing, the building is both a comfort and an ornament, and the membership is select and growing.

A. Jacobi, Chairman,

ARTHUR M. JACOBUS, Secretary,

D. B. St. John Roosa, President of the Academy and Member of the Board of Trustees,

EVERETT HERRICK.

DANIEL LEWIS,

RIOHARD KALISH, Recording Secretary of the Academy and Member of the Board of Trustees, and

FREDERICK A. CASTLE,

who adds to the foregoing the statement that the matter referred to in the editorial article is the finances of the Academy, as distinct from the funds in the care of the trustees; and that the trustees have, as such, nothing whatever to do with them or with any publication regarding them. The foregoing reference to the action of the trustees relates to the report by the "treasurer for the trustees," which was not mentioned in the editorial article.

\*\* Reference to the article complained of will show that there was no intination of any discord between the trustees and the president of the Academy. We have since learned that at the meeting at which the vote was taken to print the report on the finances of the Academy, all present voted affirmatively; so the statement that the majority so voted was erroneous. The article does not even suggest that there is ground for suspicion or concealment or that the Academy is not in a flourishing condition; on the contrary, it distinctly congratulates the administration on the excellent condition of the organization and virtually commends the example to other medical bodies.

## Proceedings of Societies.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Special Meeting of January 12, 1894.

The President, Dr. S. WEIR MITCHELL, in the Chair.

The Proposed Action of the Board of Health in Reference to the Registration of Tuberculosis.—The council, to which the resolution and amendment with reference to the proposed action of the board of health concerning tuberculosis had been referred, offered the following resolution to the college:

Resolved, That the College of Physicians believes that the attempt to register consumptives and to treat them as the subjects of contagious disease would be adding hardship to the lives of these unfortunates, stamping them as the outcasts of society. In view of the chronic character of the malady, it could not lead to any measures of real value not otherwise attainable.

That strict attention on the part of physicians in charge of the individual cases, insisting on the disinfection of the sputum and of the rooms, on adequate ventilation, and on the separation of the sick from the well, as far as possible, will meet the requirements of the situation so far as they practically can be met, and better than any rules that, for diseuses so chronic, can be carried out by a board of health.

That the College of Physicians respectfully requests that no official action be taken in the matter by the board of health, ex-

cept the insisting on the disinfection of rooms in which consumptives have lived and died in instances in which such procedure is not likely to have been adopted under the direction of the attending physician.

Dr. Owen J. Wister, who opened the discussion, said: When I offered my resolution at the December meeting of the college it was objected by those who were in favor of registration of cases of consumption that nothing was intended beyond registration in order that medical literature of a kind to warn persons of danger might be sent to their houses. In a paper read before the Pan-American Medical Congress on Tuberculosis, and published in the Medical News of October 21, 1893, there is a good deal more in reserve which is insisted upon.

Registration, in the first place, is meant to include the residences of all persons affected with pulmonary tuberculosis, and, even if the place of residence is temporarily changed, it must be by and with the consent and knowledge of the board of health.

As to the literature, so called, I think that is of doubtful desirability. Those who spent the summer of 1892 in town, when there was a cholera scare, will remember that there was a great deal of this sort of literature—the papers reeked with it. The evening papers published articles of such a sensational character that the health officer was lashed into such a state of hysterics as to propose a quarantine against New York, under the act of Legislature which makes such a proceeding lawful when a contagious disease is "raging in a neighboring city." The "rage" in this case amounted to four cases in a population of a million in a month. This proposition, however, was not adopted. But, while the board of health was thrown into spasms of terror, there was enough that was ludicrous in this literature to throw the community into spasms of laughter, and we had a rather cheerful summer. It can not be hoped that this view will always be taken when, instead of a scare of two or three weeks, it will last ten or fifteen years, while from forty to fifty are dying a week. It is then possible that this literature may lash the whole community into panic, and that, instead of regarding the unfortunate victims of consumption as objects of compassion, they will be looked upon as peripatetic fountains of danger, and a feeling of hostility to them will arise. This may last for years, for during the whole period of softening they are regarded as sources of danger. In fact, they are to be treated as criminals guilty of consumption. As I said before, their residences, however temporary, are to be disinfected and their miserable lives are to be rendered more wretched by being haunted by the familiars of the inquisition. It is asserted that if these radical measures are carried out tuberculosis will be eradicated in a few years; of that, it is said, there is no doubt. Now, no other contagious disease has ever been extinguished, even with the added protection of vaccination in small-pox. Those of us who are not in the intimate confidence of Nature find it difficult to understand how a hereditary disease can be eradicated by measures which only limit its spread by contagion; and if it is not hereditary, whence come those forms of tuberculosis other than pulmonary? It can not be pretended that babies a year or two old get tubercular meningitis by contagion, nor can white swelling, nor suppurating glands, nor the many other exhibitions of scrofula come from contagion. I think very few of us will concur in this sanguine expectation. There are several other suggestions: one is likely to be very popular; it is that all persons working in factories and the like, who are affected with pulmonary tuberculosis in the softening stage, shall be withdrawn and, when necessary, supported by pensions. In this country we have a large experience of pensions; pensions have bankrupted

the treasury of the United States. It is easy to believe that people unwilling to work could get the necessary certificate from some twopenny doctor and be supported by the State. As to the more serious part of the matter, the treating of persons so unfortunate as to have pulmonary tuberculosis as criminals guilty of consumption is something so frightful that I implore the college to interpose its remonstrance against such an outrage on common sense and common humanity.

Dr. L. F. FLICK said: Together with other fellows, I should like to bring up the entire subject for discussion, and, without wishing to find fault with the council in referring back the resolution in amended form, I should like to offer a substitute which will bring up both registration and special hospitals for the treatment of the consumptive poor. The substitute is as follows:

Whereas, Tuberculosis is now known to be a contagious disease: and

Whereas, The methods by which the disease is conveyed from the sick to the well are now clearly understood; and

Whereas, It has been shown that the room which is occupied by a consumptive during the infectious period of the disease, and the furniture and the bedclothing which have been used by him, become infected and are liable to convey the disease to others who may occupy or use them subsequently; and

Whereas, Tuberculosis, owing to its long duration, cripples the bread-earning capacity of the family, when it occurs among the poor, to such an extent that the want and hardships which follow in its wake prepare the healthy members of the family for the disease; therefore be it

Resolved, That we recommend to the Board of Health of the City of Philadelphia the registration and disinfection of houses which have been infected by tuberculosis;

Resolved, That we recommend to the City Councils of the City of Philadelphia the establishment of a municipal hospital for the treatment of persons suffering from tuberculosis.

The question of contagion, Dr. Flick went on to say, seems to be admitted, and can, therefore, be eliminated from the discussion. I will then take up the question of prevention. In reply to what has been said by Dr. Wister, I may state that the paper from which he quoted was a scientific paper covering the entire subject. He ought to have told you that the author pleaded in that paper only for a beginning in preventive measures.

The contagion of tuberculosis being admitted, what measures are necessary for its prevention? The careful investigation of this subject from many points of view by Dr. Cornet, Dr. De Forest, and myself shows beyond doubt that there is a local infection-that the consumptive in his home is sure in his ordinary daily life to infect his room, the furniture, and the bedclothing. The experiments made by Cornet illustrating this subject are most elaborate. They covered a period of two years, during which time he perseveringly followed out his line of research. He examined the dust gathered from the floor, the walls of 'the room, the bedposts, and the bedclothing of persons in advanced stages of consumption confined to their beds. He found that by inoculation with this dust he was able to produce tuberculosis. He found, moreover, that where a patient was sufficiently intelligent and obedient to follow the instructions to always spit in the sputum cup and never into a handkerchief or on the floor, inoculation with the dust produced no effect; but where the patient occasionally spat into a handkerchief or into a nook in the room, inoculation with dust from the surroundings of these places was effective. He was able to demonstrate that in proportion to the obedience and cleanliness of the patient the extent of the infected environment decreased. Where the patient was cleanly and took ordinary precautions,

but not absolute precautions, the infection extended to only a limited space—possibly four or five feet. Where the patient was uncleanly and spat indiscriminately, not only the bedposts and the floor, but also the walls were capable of conveying the infection. The clinical investigations which I made in this city, and some illustrations which I shall throw upon the screen, and the clinical investigations made by Dr. De Forest in New Haven, corroborate these results in such a way that their meaning can not be misunderstood.

[Here the speaker gave an account of his observations in the Fifth Ward of Philadelphia and of Dr. De Forest's observations in New Haven.]

Now, this evidence, the speaker continued, of infection and retained infection of houses, together with the demonstrations made by Cornet, can point to only one conclusion, and that is that the houses which have been inhabited by a consumptive for a given period will retain the infection and convey it to others. I have investigated quite a number of cases which illustrate the same point. I have knowledge of a telegraph office in Maryland in which five consecutive operators contracted tuberculosis and died. The results in these five cases were so striking that people became superstitious in regard to the office. I have been informed by a person who saw the office that the consumptives had spat around the office, and that it was lined with tubercular sputa. I have been able in this city to trace a great many cases where persons innocently moved into houses unsuspicious of any infection, and where, within six months, a member of the family who was healthy before had taken the disease, and the case had been followed by others.

Dr. De Forest mentions a very striking result of his investigations in New Haven. He investigated the histories of a hundred persons coming to the medical clinic of the city, and found that fifty-two were living in infected houses. In 1888 I carefully examined the deaths that occurred in the Fifth Ward during that year. There were eighty-three bona fide deaths from consumption. Although out of the 3,500 houses only 650 were infected, two thirds of these cases occurred in these infected houses. Of the remaining third, a large number of the patients had lived in infected houses and had changed their residences, so that apparently more than two thirds of the persons in whom death occurred in 1888 had contracted the disease while living in infected houses.

If the statements I have made are true, how is it possible to institute any practical preventive measures without registration? The education that is spoken of in the resolutions offered by the council will not accomplish much. Cornet has shown that even where the patient has carried out most of the instructions the immediate surroundings are infected. As you are well aware, among the very poor there is no nursing. The consumptive is apt to lie on a bench in the kitchen-a small room, perhaps eight by twelve feet. He has to wait on himself, and probably spits indiscriminately. Under such circumstances he is sure to infect the room, and it has been shown that the disinfection of such a room can not be effected by burning sulphur, but special methods are required. One of the most efficient methods is by rubbing down the walls with dry bread, and then washing with carbolic acid or some other powerful germicide. The furniture and the bedding also require disinfection. You well know that the houses in which the poor live are owned by men who are trying to get as much money as possible out of them. The owners will not disinfect these houses if they can avoid it. It is only by the authority of the government that this disinfection can be accomplished.

Now, is the profession ready to step forward and say, "We will make an earnest effort to stamp out tuberculosis"? The profession throughout the country has said that it would. The

American Public Health Association, during its session in Chicago, adopted resolutions asking that registration should be practiced. The Section in Hygiene of the Pan-American Medical Congress adopted similar resolutions. The Congress of Tuberculosis, in Paris in 1888, passed resolutions asking that tuberculosis be recognized as a contagious disease, and in 1891 passed a resolution asking that disinfection be practiced.

Will disinfection have any effect? It will. I should like to cite one illustration. So far as I know, Berlin is the only city that has taken scientific precautions against tuberculosis. The result is most encouraging. In the city of Berlin there has been a marked reduction in tuberculosis from 1884 to 1891-a more rapid reduction than in any other city of which I can obtain statistics. In Philadelphia there has been a reduction. In London there has been a vast reduction since the establishment of consumptive hospitals fifty years ago. Whether or not registration is being enforced in Berlin I do not know. I have been told by private parties that it is. Contrasting the reduction in Berlin with the reports from other cities, we find that the mortality in Paris was about the same in 1890 as thirty years prior. Whether or not France will succeed in establishing preventive measures is yet to be known. I have had no definite information on the subject.

As to the sentiment on this question, it is all on the side of registration. I grant that it may be hard for wealthy people to be recorded as suffering from tuberculosis, but this is a disease of the poor; the vast majority of consumptives are very poor, and the necessities of the poor so demand registration that it should outweigh the sensitiveness of the rich. But the sensitiveness of any one can be overcome by the suggestion embodied in the resolution I have offered, a suggestion which was made to me by Dr. James C. Wilson—that is, instead of registering the individual, to register the infected house. It would then not be necessary to register tuberculosis among the wealthy, as only houses that had been infected would have to be registered? Where infection can be prevented by proper sanitary measures there would be no occasion for registration. This would enable us to register those houses that needed to be disinfected.

The best place to study this subject is among the poor. It is there that I have learned my lessons. I am satisfied that every man here will reach my conclusions if he will go among the very poor and study this question at the bedside, and see how, one by one, these people die from the disease because they are unable to protect themselves, and because in the endeavor to protect and supply medicine to the stricken one the healthy fall victims to the disease. It is they that need aid. The College of Physicians should now take a firm stand and do something in aid of these people. It is not necessary to do everything at once. Let us make a beginning. Experiments have been made; let us now come to action. It is not fair to the public that the medical profession, with the knowledge it possesses, should do nothing. The laity can not act, because they have not the knowledge. If we who have the knowledge do nothing, we are certainly responsible for the deaths of those who otherwise might be saved.

Dr. J. M. Da Costa said: Let me say, in the first place, that I thoroughly admire the enthusiasm which Dr. Flick has for years brought to the study of this question. I think that the way in which he has gone about this work is in every respect most commendable, and in its spirit and scope this is one of the best series of observations with which I am acquainted. If I differ with him, it is rather in the conclusions than with reference to his mode of investigation and his aims.

When we speak of contagion in consumption we can not mean that it is markedly contagious. There is no proof that it is. It is not contagious like typhus fever, or small-pox, or

scarlet fever, or diphtheria. It is only slightly contagious. It is, indeed, so slightly contagious that some of our best thinkers with the largest fields of observation, notwithstanding the evidence that has been adduced, still hold that it is not contagious at all. For instance, if we take the opinion of a man so long connected with the Brompton Hospital as Dr. Williams, we find in the last edition of his work on Pulmonary Consumption that he maintains that no more deaths from consumption occurred in the attendants of the Brompton Hospital than occurred among the same number in ordinary life. The evidence of Dr. Andrew, of the Victoria Park Hospital, is in the same direction. When we look at the conclusions of these men and at those of Wilson Fox and many others, it is going too far to assume that the whole profession admits the disease to be contagious.

That it is moderately so, and that it can be communicated under exceptional circumstances, I firmly believe; but that we should regard it as a very contagious disease and take all the precautions that we do in such diseases, I deny. If it is contagious, it is contagious, as every one admits, chiefly through the sputum. Is it to be understood that an inspector from the board of health is to come daily to take care of the sputum cup? Is not the intelligent physician the proper health officer? Is not what he says sufficient, and can he not advise and enforce the destruction or the disinfection of the sputum as well as any public officer? Finding bacilli in the bedclothes and on the bedstead, and destroying them, will not eradicate consumption. Tubercle bacilli are widely diffused. They are in the dust of the air we breathe, blown about from the dried sputum of consumptives in the street. They have been demonstrated to exist on the fruit sold in our markets; they are in milk. They may, indeed, be said to be everywhere; and not only in the homes of consumptives. They have been found in churches, in places of amusement. Where will you draw the line as to watching and interfering with the life of the consumptive? Must we not take the broader view, and act on the degree of the communicability, and how far it is practicable to control it, rather than on the mere abstract question whether tuberculosis is contagious or not? The degree, every observer knows, is extremely slight.

The excellent series of observations about the houses is, I believe, subject to several fallacies. In the first place, unless you know the history of the persons themselves, these observations on the houses supposed to be infected are not conclusive. You must know whether or not the individual inherited tuberculosis. I am one of those who believe that the disease is largely hereditary. Of what use is it to say how many living in these houses die of consumption unless you know the history as well as the number of those who have occupied them?

Again, we should bear in mind, when discussing the contagiousness of phthisis, how enormously prevalent the disease is, and how difficult it is to draw conclusions when you have the most prevalent chronic disease to deal with. As bearing upon the question of infection from husband to wife, it bas been calculated by Longstaff as a mere matter of statistics, without reference to the question of contagion, that of every 148,-121 men who die of consumption in the ages of married life, there would be 4,358 wives who would have consumptionthat is, about 1 in 33. Thus for every thirty-three married men who die of consumption there would be one woman have it, as a mere matter of ordinary frequency, whether the disease was contagious or not, and the probability would be a little more for phthisical wives. The number of cases seen in which both bushand and wife have been affected is comparatively small. Flint, in over six hundred and seventy cases, noted but five such instances. My record shows more such instances, including one where a tubercular husband had three tubercular wives. Still I have not met with very many, and the chances are always slight that the husband will communicate the disease to the wife, or the wife to the husband. When we take all these facts into account, as well as the strong hereditary tendency of the malady, we must be careful how we draw con clusions in individual instances of apparent contagion.

Mindful of the observations of Dr. Flick, I have for some time questioned myself with reference to houses that I have known for years in which there has been consumption. But I have not taken them in one district, but everywhere. And this seems to me a much fairer way of studying the question, as the indiscriminate selection obviates the likelihood of error from bad hygienic conditions, especially of drainage, that houses near each other might share.

I have many houses in mind in which no case of consumption followed the first. In one, the father died of a slow consumption twenty years ago. The mother is, as regards tubercle, perfectly healthy to this day. The seven children have grown up into exceptionally healthy young men and women. In another house the wife died of consumption about eighteen years ago. The husband continued to live in the same house, and a family of children have grown up healthy. Another house has been occupied for many years by a consumptive who has had the disease for twenty-five years. Neither his wife nor any of the five children has become affected, though he is in the hands of a physician who does not believe in the contagiousness of the disease, and does not direct the sputum to be disinfected. Another house was occupied for years by a consumptive mother, whose husband had died of the disease many years before in another city. The son and daughter remained in the house mentioned for eight years in perfect health. It has since been occupied by a lady whose history I know, who is also healthy. The son got married about seven years ago, and has lived in various places. Within the last two years he has become a consumptive. His strong hereditary tendency determined it. I could go on citing instance after instance. I admit they furnish negative evidence. But negative evidence in a matter of this kind is valuable. I am on the whole quite certain that in by far the larger number of cases where I have known the history of both the house and the household for a long time, there could not even be any suspicion of house infection. It is true also that in most of the houses cleanliness and ventilation were well attended to

Further, in the question of house infection, we must not overlook the fact that these supposed centers of infection may adjoin, and have common drainage. And, under any circumstances, does it not suggest that possibly there is something wrong in the drainage or subsoil as much as it does infection of the house? The well-known observations of Bowditch and of others have made us familiar with this mode by which consumption spreads in Massachusetts and in the whole of New England.

With reference to hospitals: Consumptive hospitals have been brought forward as a strong evidence of the non-contagiousness of phthisis, though I can not say that the figures they adduce are to me absolutely convincing, and there may be something in the greater prevalence and concentration of the poison that make consumptive hospitals more likely to be sources of infection. I have already referred to the observations and opinions of Dr. Williams and of Dr. Andrew. But as regards general hospitals in which consumptives are, they certainly can not be shown to be places of infection. I will quote the remarkable results in the General Hospital of Vienna. That hospital is one of the largest in the world. It is full of consumptives, and there were, as we know by some observations made long since, and before the disinfection of the sputum

was attended to, in three years two thousand seven hundred and thirty-six deaths from phthisis, and not a medical officer or a nurse had become infected. I will refer to the record of the Pennsylvania Hospital, which always has consumptives in its wards. I have taken some pains to ascertain the truth in this matter. In my long connection with the institution there never has been a time when there were not cases of tuberculosis in the medical wards, and there have also been cases of surgical tuberculosis in the surgical wards. Of a hundred and forty-seven resident physicians that have been in the hospital in the last seventy years, of whom I have traced the medical history, and many of whom I have personally known and examined, but one has died of tubercular disease. Two others have at different times shown tubercular symptoms. One of these is now living in Arizona in fair health. In the other, even bacilli have disappeared from the sputa. The one that died did not die for over five years after leaving the hospital. Moreover, before becoming a resident physician, he was in delicate health, so that it is not fair to attribute his death to his having been in the hospital.

A stronger statement still can be made with reference to the nurses. Of forty male nurses that have been in the hospital in the last twenty-five years, but one has shown any sign of tubercular disease. He is now a patient in the hospital. He did not become tubercular until four years after leaving. There have been a hundred and sixty-three female nurses whose histories can be fairly well traced. Of fifty-three that have left the hospital in the last five years we know the present condition accurately. Not a single one of these certainly has had any tubercular symptoms, notwithstanding that there was always tuberculosis in the wards, always some exposure, and until recent years disinfection of the sputum was not practiced, although ventilation was always attended to. There is only one case even doubtful. One woman has an occasional cough, and is not strong. Her father and mother both died of consumption.

When we take all these facts into account, granting, as I do, that up to a certain extent tuberculosis is contagious, I think that the recommendation of the council to the board of health is the right one. Why fix the brand of leper on a poor unfortunate because he has consumption, when the medical officer can do all that is necessary? He can instruct how to ventilate and keep the house pure, and how to disinfect the sputa. What more could a board of health do? What can it do, except in instances of death where proper disinfection may not be carried out? Where death has occurred, and where disinfection is not likely to be practiced, it would be proper for the board of health to interfere. Under other circumstances why should we place a stigma on the consumptive, why have him pursued from house to house, why have him a marked man, or why have the house a marked one? Why give it a bad name and injure the landlord because there has been a death from consumption in it? I think that the resolutions offered by the council cover the whole case. No human being will suffer. It will only enforce on medical men the necessity of insisting on proper disinfection and proper hygiene. It will do as much as possibly can be done, and as much as any board of health

With reference to hospitals for the consumptive, there is a great deal to be said on both sides of the question. Undoubtedly better means of separating the sick from the well are desirable. But whether this can be made in any way obligatory is doubtful; large social questions and questions of finance arise which take the matter far beyond our power to influence materially.

We must not overlook the strong hereditary tendency to

the disease. If you want to get rid of consumption, it is not going to be simply by the disinfection of sputa and similar means. It will be largely by the prevention of the marriage of tuberculous patients. There you strike at the root of the evil. Until hygiene, preventive medicine, and law have reached that point, I think we must let this question take care of itself, doing the best we can to limit the ravages of the disease. I admit that it would be most desirable if we could separate the consumptive from the well. If the State were rich enough to make colonies in climates in which consumption will not flourish, that would be a most admirable means.

Let me say that it is not because I do not believe that phthisis is communicable that I oppose the contemplated action of the board of health to declare the disease contagious and to register consumptives, but because I believe that the means proposed will produce hardship without corresponding value, and that they are both unnecessary and insufficient. The board of health has already the right, and may well enforce it, to have any house that, whatever the cause, has a bad sanitary record, put in better order. Moreover, it can do much in destroying other sources of infection, such as from diseased meat, from the milk of tuberculous cows, in improving drainage, in favoring open spaces that air and sunlight may get into houses. But let us leave the care of the individual where it belongs—to the conscientious physician.

Dr. John B. Roberts said: It seems to me that this question is almost exactly the same as the one with which surgeons struggled ten years ago. I was one of the conservative ones who did not at first practice antisepsis, but employed half-way measures and saw all my cases suppurate. This is the point to which the question of tuberculosis has come.

I think that Dr. Da Costa's statement that there are a large number of eases all over the country, which he uses as evidence that the disease is not certainly infectious, is really an argument on the other side. It is so because there is infection. There are so many hereditary cases because infection of the parents has so weakened the tissues that a lowered resistance is transmitted to the children, and they can not repel the action of the bacilli.

It is said that the doctor can do all that is necessary, but Dr. Da Costa has said that he has known of cases where the physician would not take any precautions. That is the reason why the board of health should step in among the poor and see that the houses are clean. We see this in diphtheria. It is not a question of damage to landlords. It would be an advantage if every one knew that every house was disinfected, either by the willing efforts of the people, or of the owners, or by the board of health. There seems to be no reason why there should not be a report to the board of health if it will act in a reasonable manner. There is no expectation that the board of health would take the same measures as in typhus or typhoid fever. It is only a few years since typhoid fever was placed on the contagious list. If the matter had been discussed publicly there would no doubt have been many men on both sidessome for and some against putting typhoid fever on the infectious list.

It might be well to mention what has been done in other places. In February, 1892, at a conference of the medical staff of the Manchester (England) Hospital, with the medical officers of health and others, it was unanimously resolved that it was desirable that certain cases of phthisis should be notified to the medical officer.

Dr. Herman M. Biggs, the chief inspector of pathology, bacteriology, and disinfection in the health department, has sent to the health board a long statement regarding the contagiousness of tuberculosis, accompanied by a number of recom-

mendations. [The speaker then read Dr. Biggs's statement, which we have already published.]

The North London Hospital for Consumption, Dr. Roberts continued, issues directions to its out-patients and to its ward patients, recognizing the contagious nature of tubercular phthisis and suggesting precautions.

The Royal National Hospital for Consumption, Ventnor, says: "Patients are earnestly requested not to spit on the ground, floor, or fireplace, but to expectorate into the proper vessel. When this is not possible, the handkerchief should be used without fail; but, in order that the expectoration may not become dry, it has been arranged that a clean pocket handkerchief shall be supplied to each patient daily, and the soiled one removed for the double purpose of disinfection and washing. It is to be distinctly understood that spittoons shall always be used when possible, and that the handkerchief is only supplementary to prevent spitting upon the ground."

The Manchester Hospital for Consumption takes similar ground: "All matter coughed up from the chest should either be spat in the fire or should be received into a vessel lined in such a way with a piece of paper that the paper and its contents may be lifted out and burned. Rags that can be burned should be used instead of pocket handkerchiefs, and if a pocket handkerchief is used it should be well boiled before the matter upon it has had time to become dry and powdery. N. B.—The medical officer of health for Manchester undertakes to purify, free of cost, any house that may be notified to him by competent medical men."

Last year the Northwestern Branch of the Society of Medical Officers of Health drew up a memorandum on the subject, which has been pretty widely distributed in the North of England. In this memorandum the infectious nature of consumption is definitely laid down, and dried sputum in the form of dust is indicated as the vehicle of contagion.

The County Borough of Oldham, in England, gives similar "precautions against taking consumption."

The French Lique préventive contre la phthisie pulmonaire says: "The most frequent and powerful source of infection lies in the expectoration of consumptive patients. Although almost harmless so long as they remain in the liquid state, the sputa become especially dangerous when they are reduced to dust. They quickly take on this form when they are projected on to the ground, the floor, and the walls; when they soil clothing, counterpanes, bedclothing, critains, etc., and when they are received into handkerchiefs, napkins, etc."

With this evidence of scientific work in other places, can the College of Physicians of Philadelphia deny the contagiousness of phthisis, or doubt the advisability of the board of health knowing and registering the houses of at least the poor and careless, in which the germs of tubercular consumption are threatening the public safety?

While there may be a few who believe in the non contagiousness of consumption, the vast majority does believe that it is contagious to a certain extent. It is the same old story of antisepsis and sepsis. The College of Physicians should go on record that consumption is contagious more strongly than appears in the report of the council. In the second place, something should be done. That, it seems to me, should be in the direction of letting some official know that consumption bacilli are to be found in a certain locality. Not the physician, but some central authority should have the authority to know and the authority to enforce such measures as will limit the spread of the disease among the poor. If we limit it among the poor, we limit it among the rich.

Dr. William Osler, of Baltimore, said: The question may be thus briefly stated: 1. Following a primary law of parasitism, the Bacillus tuberculosis frequents chiefly that organ in its host which communicates most freely with the exterior. Just as countless thousands of ova are thrown off from the intestine of the bearer of a tapeworm, so from tuberculous lungs in a state of softening and cavity formation, countless millions of bacilli are cast out daily with the sputa.

2. The widespread diffusion of the parasite outside of the body has been demonstrated in the infectiveness of the dust and of the scrapings of the walls of rooms and wards occupied by patients with pulmonary consumption. Moreover, the greater prevalence of tuberculosis in crowded communities, the enormous mortality from the disease in prisons and institutions, and its frequent occurrence as a house malady, suggest that the conditions favoring its continuance are those which foster the growth and spread of a specific contagion.

3. In the language of parasitology, the lungs constitute the chief seat of election. But, apart also from gross pulmonary lesions, the proportion of autopsies in which the bronchial glands are found tuberculous speaks unmistakably for direct infection in the exercise of their function as dust filters.

On these grounds I believe that the registration of pulmonary tuberculosis would be beneficial—enforcing attention to those sanitary details so apt to be slighted or overlooked, and diminishing directly the danger of contagion in the community.

Infection through food is closely related also to the endemic prevalence of tuberculosis. The incidence of the disease in the mesenteric glands of infants indicates that the gastro-intestinal canal is a portal of infection only a little less wide than that of the respiratory system.

The question of tuberculosis is not, however, settled with the disinfection of the sputa of consumptive patients.

The hereditary transmission of the disease must be accepted, though an estimate of the frequency of this mode of infection must necessarily be uncertain, but for certain forms Baumgarten's theory of latency is particularly suggestive. Tuberculosis has been well called the  $p\dot{e}brine$  of the human race. The analogy is striking, for not only, as you will remember, is the parasite of the silkworm disease transmitted by direct contagion, but it also infects the eggs, which hatch, and may pass through various stages of development before they are finally destroyed.

Lastly, and here is consolation, the conditions which render individuals more or less immune scarcely yield in importance to those which maintain the vitality of the tubercle bacilli in a community. So widespread is the seed that few of us escape infection, and the statistics of the Paris morgue show that in more than fifty per cent. of adults the germs not only gain an entrance, but actually effect a lodgment. As a factor in tuberculosis, the soil, then, has a value equal almost to that which relates to the seed, and in taking measures to limit the diffusion of the parasite let us not forget the importance to the possible host of combating inherited weakness, of removing acquired debility, and of maintaining the nutrition at a standard of aggressive activity.

Dr. H. C. Wood said: I came here not to speak but to learn, and thus far have been quite successful. I wish to quote from a letter from Dr. Billings which has been placed in my hands. He says: "I should like very much to hear the discussion, but probably should have little to say, since I am doubtful as to what the decision of the college should be on this point. I presume that there are about six thousand people in Philadelphia affected with consumption, and that a considerable proportion of these have contracted the disease in infected houses. If it were possible by a systematic notification for the board of health to locate a considerable number of these infected houses, what steps would it take to purify them? How would it deal with those of the poorer classes who are affected with this dis-

ease, and with their furniture, bedding, and rooms? Until these questions are answered, I do not find it possible to form a definite opinion as to whether it is worth while to put in force a compulsory system of notification. Some of the worst infected rooms are probably those occupied by the criminal class, which is especially liable to this disease. For example, the Eastern Penitentiary is certainly thus infected; but in this I presume the board has no jurisdiction.

"It occurs to me that if the system of notification is to be tried, it might be best to commence with a limited area of the city in which the death-rate is now high; for example, the Seventeenth or the Seventh Ward, and see what results in diminishing the proportion of cases in this area can be obtained in the course of two or three years."

This thought has occurred to me, Dr. Wood went on to say, and has not been touched upon by any of the speakers. In a case of diphtheria the board of health is notified. The patient dies or gets well and the room is disinfected. Suppose, however, a case of consumption: the board of health is notified, the house is disinfected to-day, but reinfection occurs to-morrow, and the end need not come for four or five years. Unless you add the power to forcibly remove the patient and shut him up in a hospital jail where you can confine and permanently disinfect him, I do not see how you are going to get any good results from the process of disinfection. So far as disinfection goes, unless you can prevent to-morrow's reinfection, I see little use in to-day's disinfection. If, however, the board of health could disinfect houses in which consumptives have died, something might be achieved, but the ordinary death notice is all the notification required for this.

Dr. Thomas J. Mays said: In the charts which are presented to us it is to be noted that the disease is less frequent in those parts of the Fifth Ward in the neighborhood of Spruce and Pine Streets, and becomes more prevalent as we approach the poorer portion of the city. Dr. Flick's investigations extended over only a limited period of time-say, twenty-five years. In that time he finds that about twenty-five per cent. of the houses in the Fifth Ward have become infected. I hold that if the investigations had extended over a longer periodsay, fifty, seventy-five, a hundred, or a hundred and twenty-five years-he would have been able to show that nearly every house in that ward was infected, according to the contagion theory, and that in nearly every house in that ward a consumptive had lived and died. The same argument holds against the investigations made in New Haven. I have in my possession a book reporting similar investigations made by Dr. Riffel in two old towns along the Rhine in Germany. He investigated the death-rate from phthisis in these towns for fifty, seventy-five, a hundred, and in some cases a hundred and fifty years back. He found that, in one town at least (Karlsdorf), at some time or other, nearly every house had had a case of phthisis in it. I think the same thing would hold in regard to the Fifth Ward of this city if the statistics extended back sufficiently long. But as these cover only a period of about twenty-five or thirty years, this is out of the question.

Dr. Flick also refers to the diminution of the phthisis mortality in Berlin, London, and Philadelphia. I think that if he had consulted the death-rate from phthisis in these cities he would have found a gradual diminution in the death-rate from consumption before the bacillus era began in 1882. I went over this subject some years ago, and I found that in every large city there was a gradual diminution in the death-rate. Dr. Flick maintains that the diminution in the death-rate of consumption since 1882 in this city has been due to the disinfection of the sputum. His own figures show, however, that there occurred a larger number of deaths from this disease during the nine years fol-

lowing 1882 than during the nine preceding years. In what way this makes a favorable showing for the theory of disintection I am at a loss to understand. So far as I know, there has been no board of health regulation in this city. So far as I know, there has been no board of health regulation in Berlin, or London, or any other city, yet their deaths are gradually diminishing in number. If the gentlemen on the other side will look backward a hundred years, they will find that the very experiment which they are so anxious to try now was tested with the utmost rigor from 1782 to about 1855 in Naples. It was decreed that every physician who neglected to report a case should be fined a hundred and eighty dollars; that the ceilings, walls, floors, doors, and windows of the room in which consumptives died should be torn out and burned; that the bedding and furniture should be also burned, and that such dwellings were not to be occupied for a year. The result was that the family with phthisis was shunned and driven to want. Houses in which consumptives died depreciated in value. The sick were neglected and left to die inhumanly away from their families and friends. Did any good result from these laws? Brehmer states: "Concerning a diminution in the rate from phthisis in Naples the medical historians of that period are ignorant." According to Uffelmann (Berlin, klin, Wochenschrift, 1883, p. 369), Dr. de Renzi, the medical historian of Italy, states that the injury which had been inflicted on Naples by these laws was simply indescribable, and denounces the Neapolitan faculty in the severest terms for participating in their introduction.

In vol. xlv, p. 112, of the British and Foreign Medico-chirurgical Review, it is stated that Dr. Spatuzzi and Dr. Somma, "who have paid great attention to the mortuary returns in that city (Naples, about 1860), affirm that one sixth or a seventh of the whole mortality is due to phthisis," and that Dr. de Renzi "marvels greatly (in 1863) that the city of Naples is fully as much liable to phthisis as either London or Paris, though the salutary condition of the climate should render it far less common."

If the death-rate from consumption was the same in Naples at the time segregation ceased as it was in other cities in which segregation was not practiced, it is self-evident that such a measure can have no influence in diminishing the death-rate from this disease.

Dr. James Tyson said: I had intended to say something this evening on this important subject, but almost every point which occurred to me has been so well treated by others that I hesitate to add anything. I admit all that has been said with regard to the contagiousness of phthisis, as determined by experiment, but as to the actual spread of consumption from one person to another as the result of association-as to the degree of contagiousness, in a word-I agree entirely with Dr. Da Costa. Admitting the correctness of Dr. Flick's studies and Cornet's observations, it still comes to this: that the physician is competent to take care of this question without the intervention of the board of health. Just as the surgeon is qualified to take care of the matter of antisepsis and asepsis in his management of surgical cases, so the physician is competent to take care of the disinfection of utensils used by consumptives and the destruction of the germs which may be the cause of the disease, the more especially as such disinfection is acknowledged to be of the easiest kind. What Dr. Roberts has just said with regard to the situation ten years ago as to sepsis and antisepsis could as well be alleged in favor of the position that I takethat the physician is competent to handle the difficulties. The surgeon did not call in the board of health to help him under like circumstances, but fought the battle alone, and won it triumphantly. The question has been studied experimentally

and chemically, and we know exactly where to put our fingers to check the spread of consumption as far as this is possible. We must attack the disease in two ways: First, the contagion must be destroyed as far as possible with the means at our disposal, and, second, we must seek to change the soil on which it is known that the bacillus flourishes by improving the general health of the individual, and thus increase his ability to repel the invader. I feel that we are entirely competent to handle this question without the aid of the board of health.

Dr. Abbott said: I have listened with much interest to both sides of the discussion, but must confess that I am not yet quite sure in my mind as to the proper course to be pursued. I am strongly inclined to the views expressed by Dr. Billings in his letter to the president. Tuberculosis is a wide-spread disease with manifold expressions, and if our efforts are to be directed against it, in the full sense of the term, the problem is certainly beset with many difficulties.

In connection with the subject under discussion, the question that has constantly presented itself to me is: If the college sees proper to recommend that all houses in which the disease is located are reported to the authorities, has it any guarantee that their conditions will be improved? The object in reporting these houses is to secure complete disinfection of them, a process requiring conscientious attention to most minute details, to say nothing of a full knowledge of the requirements of the cases. If the board of health is in a position to assure us that these demands can and will be met, then I am in favor of the resolution. If not, then we have had a long discussion with but little result.

The ultimate object arrived at in the resolution I consider as most desirable, but will it be attained if the resolution is plassed ? We have abundant evidence in justification of the belief that localities occupied by persons suffering from the pulmonary form of tuberculosis, particularly, may and do become centers of infection, and it is highly desirable that such places should receive the attention that their character demands. Much has been said here this evening concerning the prevention of the spread of this disease by disinfecting the sputum, and this point has been accentuated as if the danger ended here. The danger does not end here. Sputum collected in a receptacle may remain perfectly harmless without disinfection or any other treatment whatever. The danger lies in the sputum not collected, but spat upon the floor, dried, ground into dust by the feet of passers-by, and ultimately inhaled into the lungs-a condition of affairs often seen in dwellings of the poor. The predominance of pulmonary tuberculosis over other manifestations of the disease is certainly, in part, accounted for in this way. Dr. Da Costa in his remarks has said that "bacilli are everywhere present," and if this is the case how are we to escape them, etc.? His use of the term bacilli in its generic sense is misleading; I can hardly think he meant that tubercle bacilli were everywhere present, for this is not the case. They may be present everywhere that tuberculous individuals are present or have been present, but to say that they are present in all places does not accord with the results of observation.

Dr. Frank Woodbury said: The facts collected with so much commendable diligence by Dr. Flick are susceptible of quite another interpretation. They certainly do not prove consumption a contagious disease, or that the Bacillus tuberculosis is its sole cause. If he had confined himself to the task of showing that want of sunlight, dampness, and other malhygienic conditions were efficient causes of phtbisis, his data would have been equally applicable. Or if he had intended to prove that the habitations of some of the poorer inhabitants of this city were likely to act injuriously upon the occupants, so as to predispose them to phthisis, we might have been willing to

go with him almost to any extent in making application to the board of health to destroy these sources of disease. We might admit that by adopting such drastic measures the mortality from tuberculosis would undoubtedly be greatly reduced. The total extinction of pulmonary consumption, under present conditions of civilized life, however, is entirely impracticable.

It may be admitted, if the proposed plan of registration and inspection were rigorously carried out, that the results would apparently support the claims of the author. The number of cases reported would certainly diminish to a remarkable degree; but the real explanation, however, of the diminution would be that a large number of cases would be concealed, and deaths would be reported as from other causes. Moreover, a large number of cases would object to the solicitude of the board of health for their welfare and leave the city. Physicians would have their sympathies appealed to by relatives, who might wish to conceal from the patient the fatal character of the malady, and would be in a dilemma between duty to their patients and duty to the State. In fact, registration would eventually divide physicians into two classes-those who reported their consumptive patients and those who did not. The physicians having the reputation of not reporting their cases would naturally have a larger clientèle than the others.

The discussion of the registration of consumption manifestly brings up the question of the nature of phthisis. It is true that there are other clinical conditions which resemble tuberculosis of the lungs and which are not due to the presence of tubercle bacilli. Assuming, however, for the moment that all cases of consumption are tubercular, we may ask how large a part in disseminating the disease is played by contagion? We know that Dr. Brush calls attention to an infected milk supply as the principal source of tuberculosis in our cities. Bowditch showed conclusively that dampness of the soil was a very powerful factor in the causation of phthisis. Other authors maintain that it is mainly due to inheritance. If these views may be regarded as well established, then the infection sinks to a secondary place. If tuberculosis is the pébrine of the human race, as has been stated, this invites a consideration of the subject from the standpoint of comparative pathology. If phthisis is analogous to the fungous diseases of the lower animals and plants, then the results of treatment in the latter may throw light upon the therapeutics of human tuberculosis. In a communication made by Dr. George B. Wood, in 1869, to the American Philosophical Society he referred to a discovery which he had made, and which, I think, has a very important bearing upon this subject. He proved by experiments upon a large number of fruit trees, which were prematurely dying by progressive decay (now recognized as some form of fungous disease), that by simply adding potash to the soil the trees were restored to their early vigor, and they resumed fruit-bearing; in fact, the crops were larger than ever before, "many branches breaking down with their load of peaches." This is a striking illustration of the importance of supplying to the soil some chemical agent which may be deficient, rather than devoting our time and energies to the destruction of germs. Pulmonary consumption certainly is curable. How many have been cured solely by an antiseptic or a parasiticide treatment? Not one; but many have been restored to health by hygienic methods alone.

Recent investigations into the ætiology of tuberculosis seem to lead us away from the germ theory, and to point to the fact that in the tissues of the phthisical patient some chemical agent is deficient, which, if we can supply, the symptoms will disappear and the case will proceed to recovery. This agent may not be the same in different patients. Cases of consumption have been cured by the hypophosphite treatment advocated

by Churchill; others have been restored to health by alcohol; yet others have been equally improved by drinking blood at the abattoirs or by eating raw beef. Cod-liver oil, advocated by Bennett, seems to supply the needed element in some; an abundant milk diet has been successful in others. The agent may be a simple salt like lime hypophosphite or sodium phosphate, or organic in its nature like tuberculocidin or nuclein. Whatever it may prove to be, one thing is certain, that the results from following out this lead have been more successful than those from parasiticide treatment. They do not strengthen the argument of those wishing to class tuberculosis among contagious diseases.

I might point out the fact that if the board of health should force physicians to make a diagnosis this would involve the compulsory use of all modern methods, including the microscope and culture-tubes. The fact has just been announced that exVice President Morton's fine herd of Jersey cattle, recently exhibited at the World's Fair, has been found to be infected with tuberculosis. It is said that the animals presented no symptoms of disease whatever, and the diagnosis was made by the subcutaneous injection of tuberculin. Can physicians be compelled to resort to this in all suspected cases in the human subject?

Dr. S. Solis-Cohen said: The question to be considered is simply this: Granting all that may be said concerning the ætiological relations of the bacillus of Koch to tuberculosis, and granting all that is said as to the spread of infection from persons affected with tuberculous disease-on the whole, will the health and comfort of the community, including both the well and the sick, be better promoted by having all cases of tuberculosis registered or by not having them registered? So far as the sick are concerned, the disadvantages of registration are obvious. So far as the well are concerned, my distinguished teacher, the vice-president of the college, has shown that the reasons advanced in support of the proposition that it is necessary to have cases of tuberculosis registered in order to protect the health of the community, can not withstand critical analysis. I believe, moreover, that registration would be a detri ment to the community, for the reason that when of two measures to prevent an evil, attention is concentrated on the less efficacious, the more efficacious is likely to be neglected. If we direct our attention too strongly toward germicidal measures we shall lose sight of the more important measures that relate to the general sanitation of cities, of houses, and of individuals, Tuberculosis among men is to be prevented by increasing the vitality of the race, by preventing the marriage of tuberculous and otherwise untit persons, and by perfecting the sanitary environment and life of the individual. The true prophylaxis against tuberculosis begins, therefore, before conception; but as society has not reached the stage of development where such prophylaxis can be generally instituted, it becomes all the more necessary to insist upon those practical measures of individual and civic hygiene which must be our greatest dependence and to oppose whatever shall tend to obscure their importance.

As has been said by Dr. Woodbury, if Dr. Flick had started out to prove that consumption flourishes in overcrowded places and where misery, poverty, filth, and vice are congregated, his statistics could not be more admirably adapted to enforce that conclusion; but to prove that tuberculosis is contracted only or chiefly by living in houses in which persons having tuberculosis have previously resided, would require that a census be taken to find out concerning every house in the city whether at any time there had been a patient with tuberculosis living or dying in the house, and if so, how many cases had followed and at what intervals, and also to determine how many cases of

tuberculosis had developed among those living in houses where no one having tuberculosis had previously resided. Until statistics of this character are at hand, the case against the socalled infected houses, in districts where the city, the houses, and the lives of the people furnish so many potent causes of impaired vitality, is at least "not proven." But grant that the proof of infection in houses is conclusive. Suppose that the houses are thoroughly disinfected, and even, referring to Dr. Wood's point, guarded against reinfection-what have we gained? We are told-and I invite correction from Dr. Abbott, if I am in error-we are told by the highest authorities that the bacillus of tubercle is about us everywhere. It exists, save at certain altitudes, or upon the sea, or in other specially favored regions, in the air we daily, momentarily breathe. Every one is at some time exposed to the danger of inhaling it, and that it is inhaled by everybody is shown by the results of autopsies upon persons having no tuberculosis elsewhere, but in whom the bronchial glands are infected with the tubercle bacillus. I believe that, according to some statistics, the proportion of persons so infected has been placed at fifty per cent. Is it not clear that, as was said by the president of the college in his annual address, in order to make the board of health laws effective, there would have to be instituted a system of espionage so that the tuberculous patient could be followed every day from the time of his rising up to that of his lying down, while seated in his house, or while walking by the way, to make sure that by no possibility should his sputum be deposited in any place where it could become dry and be carried into the air-a thing which is manifestly impossible? But if instruction only is to be given and no such rigorous supervision of individuals attempted, it is within the province and within the power of the attending physician to instruct his patients, and the intervention of the municipal officer is not required.

Therefore, because of the impracticability of this registration to effect anything positively, and because, negatively, it will have the effect of diverting attention from the fact that these streets or alleys, to which Dr. Flick directs our attention, should be cleansed and widened, the houses properly drained and ventilated, the people properly fed and clothed, and otherwise protected from exhausting and depressing influences, I consider it to be the duty of the college to place its strong word on record against the proposed legislation.

Were the proposition in favor of a municipal hospital for tuberculosis, separated from the other recommendation, and properly safeguarded, I should be glad to vote for it.

Dr. Richard A. Cleeman said: One very important point has not been alluded to. Statistics show that the death-rate from the disease is almost the same in every community, year after year. If there is any diminution, it is very small. This is directly opposed to the idea of the contagiousness of the disease. All other contagious diseases vary very much in their death-rate at different times. There is only one explanation by which we can conceive that phthisis is contagious and the death-rate always the same, and that is that the whole of the community is thoroughly infected with the tubercle bacillus, and that in the community there is a fixed number who are susceptible to the disease. Just as, statistically, we can calculate how many giants or how many dwarfs are in a community, so can we estimate the number of persons susceptible to phthisis.

In this view of the case, with the Bacillus tuberculosis spread over the whole city, measures to be effective must be of a very extensive character. The mere reporting of a case now and then—for I believe the rule will be often neglected—will have very little effect. Measures to be effective must be thorough, and they are the methods of general hygiene.

Dr. James B. Walker said: We must look at the practical side of this matter, and ask what will be the benefit from registration? How much has typhoid fever in this city been diminished by the fact that we report our cases? Not in the least. The disinfection of the stools which the physician has directed has lessened the number of cases, as similar attention to the sputum may in phthisis. I am against placing phthisis on the list of diseases to be reported, for many reasons. I do not believe that this would confer a single benefit upon the city or its inhabitants. The physician is capable of doing all that the board of health can, without the manifold evils and annoyances of public registration. The college should go on record against the registration of the disease. It should go on record also as believing that the disease is possibly contagious, and should recommend physicians to use the most strenuous efforts to prevent the transmission of the contagion.

Dr. Da Costa said: I said that the tubercle bacilli were everywhere. A bacillus that is on the pavements and in houses, that is wafted about in the air, that exists in milk and on fruit sold in the markets, and, as has recently been demonstrated, on the very money that we handle, may well be described as a bacillus that is everywhere. The tubercle bacillus is so diffused that it can, indeed, be considered as everywhere present, and it is scarcely a figure of speech to so describe it.

With every word that Dr. Roberts has said I agree. There is not a direction he has read I would not subscribe to and endeavor to enforce as an officer of an institution or in private life. I hope, indeed, that every fellow will go away to-night imbued with the necessity of carrying out all the measures that have been brought forward with the view of destroying this scourge. But is it not better that we should do this as individual health officers than to have it done in a necessarily perfunctory manner by a board of health? The only way that the board of health could radically act to destroy the tuberculous material would be to burn every house that was supposed to be really infected, separate the tubercular husband from the wife, take every child away, and cause such an upheaval in society as no community would submit to.

Dr. FLICK said: Dr. Williams, of the Brompton Hospital, has been quoted as an opponent of the theory of contagion, but he has written a paper in which he shows that a large number of nurses of the Brompton Hospital have contracted tuberculosis. I think that he has traced some fifteen or twenty cases.\*

As to the ubiquity of the tubercle bacillus, Koch and Cornet have disproved it. They have shown that the contagious environment of tuberculosis is limited. Cornet has made experiments with dust taken from the streets and many other places at random, and was unable to produce infection by inoculation. He has, moreover, made an investigation of the health of the street cleaners of Berlin and has found them freer from tuberculosis than any other class. It must be borne in mind that the isolated cases of infection of fruit and other articles which have been referred to are traceable to handling by consumptives. Many of the fruit-stand dealers have consumption.

With regard to the endeavor to ascribe the occurrence of the disease in certain houses to dampness, that can be disposed of in a moment. If you will take one of the worst-infected streets in the Fifth Ward, say Bay Street, you will find that at least twenty per cent. of the houses have not had a death from tuberculosis, although the sanitary condition is as bad as in the infected houses. Dampness can have no influence here.

As regards infection in hospitals, as I have said, Dr. Williams has written a paper in which he shows that fifteen to

<sup>\*</sup> British Medical Journal, September 30, 1882.

twenty nurses have contracted the disease in the Brompton Hospital. Cornet has written an elaborate history of hospital infection. He has taken the general hospitals of Germany in which the nurses are permanent, and he finds that as high as sixty-two per cent. had tuberculosis. In my own class of residents at Blockley, sixteen in number, two died within three years of the disease, and I myself was believed for a time to be a victim.

It has been argued that we ought to trace the history of these houses for a longer period, say a hundred years. There is a limit to the infecting power of tubercle contagion. What its duration is I can not say; probably not very long. Unless cases occur within a few years of each other to keep up the chain of infection, the houses are no longer infected houses.

Italy has been quoted as an evidence of the non-effectiveness of preventive measures. I am surprised that this quotation is made so frequently after what has been written. Those who have seen my paper on tuberculosis in Italy will be in a position to refute this statement. I proved in that paper by careful quotations from contemporary authorities—and authorities that can not be doubted-that at the time when the laws were instituted, in 1782, the mortality was about 10 per 1,000, and that when the preventive measures were abandoned, the mortality was so low in the extreme southern part of Italy that it was practically nib-0.19 per 1,000. As a result, the mortality was reduced from 10 to a fraction of 1 per 1,000. Many who have written upon the subject have overlooked the fact that it is not Naples, but the Kingdom of Naples that is spoken of. This comprised the southern half of Italy and Sicily. At first the northern part of Italy opposed the view of contagion and refused to accept any preventive measures. After some years it adopted preventive measures, but even at this day the mortality in the northern part of Italy is twice what it is in the southern part. These preventive efforts proved another point, and that is the local infection. The only practices that were of any benefit in the Kingdom of Naples were, first, isolation; and, second, compulsory disinfection. The preventive measures circled entirely about the household. The Italians did not know where the infection came from, but adopted crude measares of prevention. Yet with their crude measures they reduced the mortality to a minimum, and, except for the fact that Italy became a health resort for consumptives, it probably now would have no tuberculosis. If you will study the statistics you will find that those parts of Italy that are health resorts for tubercular patients increase the mortality. This has been as high as 4 per 1,000 in some of the resorts; but if you take the rest of the Kingdom of Naples, the mortality is a fraction above 1 per 1,000.

As to the competency of the physician to meet this question. In connection with this subject, we must bear in mind that every infectious disease is a law to itself. It is not fair to apply to tuberculosis the laws which govern diphtheria, smallpox, etc. The infecting material in tuberculosis is easily controlled. It comes from a single source. In small-pox it is difficult to control. If it were possible to sterilize all the sputa of consumptives we should not need disinfection. Such a thing is impossible, however, and therefore it is necessary that the room be disinfected. This requires great care, and, unless the family is willing to undergo the expense, it can not be accomplished. If the physician were to devote half of his time to bring about proper disinfection he could not do it effectively.

Dr. Cleeman has advanced an argument against contagion which, strange to say, has been made for the other side by Dr. De Forest. Dr. De Forest maintains that, inasmuch as the number of infected houses is limited, the mortality-rate should remain the same every year, because the number of exposures

remain the same. The centers of infection remaining the same, the deaths should remain the same.

Tuberculosis and typhoid fever have been compared. The reporting of typhoid fever can not bring about any results unless the lessons taught are acted upon. If the water supply were made better we should have no typhoid fever. There is no analogy between typhoid fever and tuberculosis. Tuberculosis is infectious from the point at which it exists; typhoid fever infects our drinking water. There is little danger from the room occupied by the typhoid-fever patient. The cases are not at all analogous.

After further remarks by various speakers, a vote was taken, and the original resolutions, as proposed by the council, were adopted, and the president was requested to appoint a committee of five to present them to the board of health.

## Miscellany.

Hotel Hygiene.-At a recent meeting of the Société normande d'hygiène pratique, the proceedings of which are reported in the Normandie médicale for January 15th, M. Percepied read a paper on the transmission of infectious diseases in hotels, where the bedrooms are occupied in turn by invalids and healthy persons. It is principally in reference to the watering places or the winter resorts that the attention of physicians and of the public has been aroused, he says, and in a number of resorts the suggestions mentioned in his paper have been adopted and have given rise to reforms, still in their infancy, but destined to extend rapidly. It is a great mistake, in his opinion, to limit hygienic precautions to health resorts only; all hotels, whatever they may be, should have the same rigorous care. The condition of health of the people received at these hotels is not known, and, granting that acute infectious diseases are relatively rare, it is certain that invalids with chronic diseases, such as tuberculosis, are frequent patrons, and the fact that the majority of the travelers remain only a short time can not be brought forward as an argument. They have the right to remain as long as they please, and they also have the right to demand that all sanitary precautions shall have been taken in the rooms that they occupy.

The subject under discussion applies only to travelers, although there is much to be said with regard to hotel kitchens and lavatories, and, above all, to the condition of health of the cooks and the other employees who live there. M. Percepied confined himself to saying that kitchens should be provided with draught flues, and be sufficiently well ventilated for the odors not to pervade the hotel.

Infectious diseases are due to germs that are very unyielding and retain their virulence for a long time, and these germs may be in every part of a room that has been occupied by an invalid; in the bedding, as well as on the walls or on the floor. Knowledge of these facts imposes the necessity of modifications in order to render the rooms habitable and free from danger to those occupying them. First of all, the room should afford air in proportion to the number of persons occupying it, and should be well ventilated and sunny, for the importance of sunlight and air as hygienic factors is well known. The walls should be hard-finished or coated with an impermeable paint which can be washed, and, so far as possible, all corners should be rounded to make them accessible to washing. Moldings, unless rounded, should be discarded. Carpets should be rigorously prohibited, and a parquet floor which can be washed substituted, or a

covering of linoleum of an artistic and pleasing design used. An advantage to be gained by this is the abolishing of the spaces which always exist between the boards of an ordinary wooden floor. If the traveler desires to be more comfortable, he can have a movable carpet or rug, on condition that after his departure it is beaten and passed through a disinfecting bath before it is used again. The same precautions should be taken with regard to carpets. In rooms that are not very much used a heavy linen covering can be substituted for carpets, which can be sent to the wash like clothing. For the same reason curtains should not be tolerated, except those that can be washed. White ones are preferred, as the monotony can be relieved with a border of embroidery in bright colors. Heavy materials, like plush and velvet, should never be used. The furniture should be very simple in design, so that it can be cleaned easily. Wooden furniture, wardrobes, bureaus, and toilet tables should be varnished or waxed, or, if preferred, lacquered. Chairs should have caned bottoms. Thus it is possible to conform strictly to hygienic laws, and at the same time preserve an artistic appearance. Everywhere, where it is possible, brass or iron bedsteads should replace those of wood. Toilet articles, especially the glasses, should be washed every day with the greatest care. After the departure of a patron they should be washed in an antiseptic solution, such as a halfper-cent, solution of corrosive sublimate, and the bedding, towels, etc., boiled in alkalinized water. With regard to the means of lighting hotels, electricity is to be preferred, although that is a question of secondary importance. The heating should be with wood, coal, or coke.

After a room has been occupied by an invalid, all the bedding and other linen should be sent to the disintecting bath, and the walls, boards, and furniture submitted to antiseptic washing and antiseptic spraying. These precautions should not only apply to the bedrooms, but extend to the different rooms that the parrons have used, although with less strictness. The curtains of the parlors, where they remain but a short time, do not require such rigorous treatment. Nevertheless, draperies should be avoided and carpets prohibited. The same precautions should be observed in the dining room. Here particular care should be given to the washing of the glasses, the forks, and the spoons. The former, after each meal, should be washed in an antiseptic liquid, and afterward well rinsed in clean water, and the latter in boiling water.

The vestibules, halls, and stairways should be without carpets and should be wiped every morning with a cloth wet with an antiseptic liquid. The closets should be large and well ventilated, and have proper appliances for flushing.

These precautions should extend to the rooms of the employees, where the sanitary conditions should be under the strictest surveillance. As soon as a case of sickness is discovered isolation should be practiced in order to take the necessary precautions as regards disinfection. These are the measures, the author says, which should be resorted to at the present time, and failure to do so shows a culpable indifference.

At first it may seem that these precautions would be a source of expense to the hotel keepers, but the abolishing of curtains, carpets, and furniture covered with rich silks and velvets will prove economical for them in the end, and, if they are properly carried out, any danger of infection will nearly always be averted.

Pericardial Symphysis in Children.—In the Union médicale for January 16th there is a summary of an article by M. Mussy, published in La Médecine moderne, in which the author states that pericardial adhesions may exist in early infancy and in the new-born, but their frequency increases very much after the

age of eight years. The cause is always a rheumatic or tubercular pericarditis. Total blending of the layers, unless it is very firm, does not embarrass the expansion of the heart, but, on the other hand, partial adhesions may involve numerous functional disorders. The signs of it are not very distinct, and often the condition is not ascertained before death. Hypertrophy is far from being the rule; when it exists, it affects the ventricles more particularly. The diastolic impulse is enfeebled or absent; it may be replaced by a diastolic souffle at the base, which is attributed by M. Potain to evaporation of the blood in a heart dilated and fixed. Changes of posture do not cause the position of the apex of the heart to vary, and that is an important sign if associated with absence of a retreat of the heart from the wall of the chest during inspiration. Systolic depression of the precordial region which replaces the impulse of the apex is characteristic, but this depression may exist in cases of aortic disease without cardiac symphysis. Effacement of the veins of the neck during diastole and sinking of the infraclavicular fossæ have been noted by Ferichs. The murmurs that are heard on auscultation depend upon lesions of the orifice, which are often developed simultaneously with the pericarditis under the influence of the rheumatic diathesis. Considerable value is to be attached to a reduplication of the sound at the base of the heart when it is not accompanied by a presystolic rolling sound and by the other usual signs of mitral stenosis. The course of the disease is variable. Sometimes it involves only occasional palpitation or dyspnœa, or gives rise to no symptoms at all, while in other cases it is manifested by intense dyspnœa, pulmonary congestion, swelling of the jugular veins, and cedema of the lower limbs or anasarca. It finally leads to true cardiac inadequacy, and death supervenes amid attacks of asystole. A matter of the first importance is the condition of the muscular structure of the heart, and the utmost pains should be taken to avoid everything that might overtax the organ. Every excessive exertion, as well as every excessive indulgence in eating, constitutes a danger. The patient should avoid copious meals and derangements of digestion, for the purpose of warding off the reflex effects upon the heart which are so frequent, and functional overactivity of the myocardium. The disease itself is not amenable to therapeutics properly so called; we are restricted to preventing or combating asystolic accidents. The application of revulsives, chiefly blisters, to the precordial region may to a certain extent impede sclerosis of the muscular structure of the heart.

The New York Academy of Medicine.—The programme for the meeting of Thursday evening, the 15th inst., included a paper on Scurvy in Children, by Dr. W. P. Northrup, and one on Scorbutic Pseudoparalysis, by Dr. Henry Ling Taylor.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 19th inst., a discussion on the Management of the Iris in Simple Extraction of Cataract will be continued, and Dr. Alexander Duane will read a paper on Paralysis of the Superior Rectus and its Bearing on the Present Theories of Insufficiency.

At the next meeting of the Section in General Medicine, on Wednesday evening, the 21st inst., Dr. Adolph Zeh will read a paper on the Dietetic and Therapeutic Management of Typhoid Fever.

At the next meeting of the Section in Surgery, on Tuesday evening, the 27th inst., papers will be read as follows: A New Operation for the Radical Cure of Inguinal Hernia, by Dr. A. M. Phelps; A Method of Differential Diagnosis in Œsophageal Stricture, with the Report of a Case, by Dr. H. Lilienthal; and The Production of Iliac Intussusception with Carbonate of Sodium, by Dr. R. T. Morris.

## DR. BORDEN'S ARTICLE ON THE FAT CELL.

Fig. 4.—Subcutaneous fat body of a fœtal cat at term, from a section parallel to that shown in Fig. 3. From a photomicrograph, × 125 diameters.

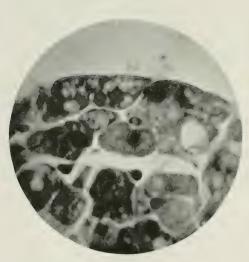

Fig. 5.—Young fat cells from the subcutaneous fat body of a fœtal cat at term. From a photomicrograph, × 750 diameters, with Bausch and Lomb '1'g-inch h. i. objective and amplifier. The focus was adjusted for the central cell.

Fig. 3.—Skin and subcutaneous tissues of a fortal cat at term. S, skin, cut somewhat obliquely, owing to curling of the tissue while hardening; M, M, muscular tissue, "panniculus carnosus"; F, embryonal fat masses. From a photomicrograph, × 25 diameters.

Fig. 6.—Young fat cells near the hair roots in the skin of a fœtal cat at term. The focus was adjusted particularly to show the central cell and its processes. There are three fat droplets in the body of the cell. From a photomicrograph, × 1,000 diameters, with Zeiss's 2-mm. apochromatic objective and projection ocular 2.

## Original Communications.

#### THE FAT CELL:

ITS ORIGIN, DEVELOPMENT, AND HISTOLOGICAL POSITION

By W. C. BORDEN, M.D., CAPTAIN, MEDICAL DEPARTMENT, U. S. ARMY.

The apparent simplicity of development of the fat cell would seem to make the task of tracing it back to its original cell form, and so determining its origin, an easy one. That this is not the case is evinced by the fact that observers are still far from agreeing what its original cell form really is. Of the many views advanced, those which assign its origin to some form of connective-tissue cell are most widely accepted and almost exclusively presented by writers upon histology and physiology.

My investigations, however, have led me to believe that these views are incorrect, and that they have given rise to erroneous ideas concerning the histological and physiological position of the fat cell.

As the facts which have led me to these conclusions are derived from observations upon fat tissue in feetal and adult, higher and lower vertebrates; it will be necessary to briefly summarize the facts of histology, embryology, and comparative anatomy relative to the form and occurrence of this tissue.

Fat tissue, or adipose tissue, as it is generally technically called, consists of aggregations of the distinctive fat cells bound together by a small amount of connective tissue and of the necessary vascular, lymphatic, and nervous supply. In the higher vertebrates it is found in various parts of the body in masses of all manner of sizes and shapes adapted to the various situations. The larger masses are divided by intervening connective-tissue sæpta into lobes, and these lobes are in like manner subdivided into lobules. The blood supply is very abundant. Each lobule has an afferent arteriole which subdivides into a meshed capillary network, the capillaries again uniting into an efferent vein (Fig. 1).

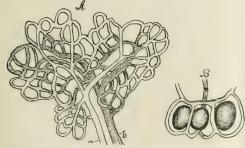

Fig. 1.—Vessels of the fat cell. A, arterial (a) and venous (b) branches, with the capillaries between them; B, the capillaries around three cells. (Frey.)

Even in the intermuscular spaces and like places where adipose tissue occurs as groups of cells having no distinct lobular formation, a capillary reticulum is present; and whenever a new formation of fat cells takes place, a more

or less distinct capillary network is developed, according to whether the formation consists of few or many cells. The resemblance between the vascular supply of adipose tissue and that of the secreting glands—such as the parotid, pancreas, and others—is most marked; for in all the vascular supply is abundant and is so distributed that each cell, whether it be parotid, pancreatic, or adipose, is in direct relation with one or more capillaries. This gland-like blood supply of adipose tissue is important when considering the histological position of this tissue, and will be again referred to farther on.

While adipose tissue is scattered through the body in the higher vertebrates apparently without design, this is not really the case, for certain regions are particularly characterized by its presence, and in others it never occurs. It is particularly abundant in the subcutaneous connective tissue, the omentum, around the kidneys, and notably in the hump of camels, which latter consists of a large fat deposit and is not in any way due to a deviation of the vertebral column. On the other hand, although connective tissue is abundantly present, fat tissue never occurs in the eyelids, penis, scrotum, nymphæ, submucous tissue of the intestine, or cavity of the cranium. Of these, the most notable instance of the limitation of fat extension is furnished by its absence from the submucous layer of the intestines, to which it never extends, though it is abundantly present in the mesentery, and at the junction of the latter with the intestine the fat deposits in it are separated from the submucous tissue of the intestine by the thickness of the muscular walls of the intestine only.

In the lower vertebrates adipose tissue is not scattered through the body at all, but is confined to certain definite localities where it is collected into gland-like bodies called "fat bodies," or "corpora adiposa." In the frog, the fat bodies are in the abdominal cavity in close relation with the genito-urinary organs. In the necturus there are subcutaneous fat tracts on the dorsal and ventral parts of the body. In the toad, besides two abdominal fat bodies like those of the frog, there is an accumulation of fat about the base of the heart, and there are six fat bodies beneath the skin on the ventral surface of the body-one at the junction of each limb with the body and two at the base of the neck. It may be considered that the intra-abdominal fat bodies of the frog are homologous with the fat masses about the kidneys of higher vertebrates, and that the subcutaneous fat tracts of the necturus and the subcutaneous fat bodies of the toad are homologous with the panniculus adiposus of higher vertebrates. It at first appears somewhat strange that while in the lower vertebrates adipose tissue is confined to certain localities, there being formed into ductless glands, as we rise in the animal scale it is not so confined, but is scattered through the body apparently in a much less purposive way. This is seemingly at variance with the general rule that segregation of like tissues is coincident with higher development. This rule, however, of necessity yields to the requirements of the organism; and the following is suggested as a probable reason why fat tissue occurs in different localities in

different animals and is scattered through the body in higher vertebrates, instead of being confined to definite localities, as in the lower.

In the lower vertebrates the amount of adipose tissue relatively to the size of the entire body is small; but pari passu with the rise in the animal scale the relative amount of adipose tissue increases, until in the higher vertebrates its proportion to the body is large. If the fat tissues of a mammal-man, for instance-were collected into two abdominal organs, as in the frog, the abdomen would have to be enormously increased in size in order to contain them, and such localized deposition of the fat tissues would greatly, if not vitally, interfere with the existence of the organism. In fact, the localized deposition of the fat tissues, if adhered to in vertebrates, would prevent in the higher types that symmetrical development of the body which is so necessary to bring it into proper relations with its environment. It appears obvious, therefore, that as the more highly developed organisms were evolved, requiring increased amounts of adipose tissue for nutritive purposes, the only way to dispose of the increased tissue was to distribute it throughout the body, filling in the connectivetissue interspaces and spreading it out in the panniculus adiposus, for in this way only could it be so co-ordinated with the body as not to interfere with organic existence or symmetry.

As the spaces filled in were those previously occupied by connective tissue, it was natural to infer that that tissue was changed into adipose tissue. This view has been strengthened by observations on starved and fed animals and on the development of fat cells in connective-tissue spaces until the theory that fat cells are developed from connective-tissue cells has gained wide credence. So high an authority as Schäfer, in the last (tenth) edition of Quain's Anatomy, vol. i, part ii, page 237, says: "It (fat) is deposited in the form of minute granules or droplets in certain cells of the connective tissue"; and Foster, in the sixth and last edition of his Physiology, part ii, page 770, writes: "It is obvious that a fat cell is a cell belonging to connective tissue, in the cell substance of which fat has collected. . . ." But, notwithstanding the seeming conclusiveness of such statements, my investigations have led me to the belief that they are based upon incorrect data, that they do not assign a proper or sufficiently important place to the fat cell, and that the fat cell is a special cell having nothing in common with connective tissue, and that it is essentially a gland cell having special metabolic functions. In support of this conclusion, the facts of comparative anatomy, embryology, and physiology relative to adipose tissue must be considered; and, in addition, the form of the fat cell at all stages of its existence must be known and taken into account.

The fat cell in its fully developed and functionally active state may be described as a protoplasmic, nucleated sac, the cavity of which is filled by a single drop of fat. The nucleus is about  $7\mu$  in diameter, and near it the cell protoplasm is thicker than at other parts surrounding the fat. A cross section of such a cell through the nucleus has been likened in appearance to a signet ring—the signet

representing the nucleus; the thickened metal setting of the signet, the accumulation of protoplasm about the nucleus; and the thinner band, the extremely thin protoplasm covering the fat drop (Fig. 2, C).

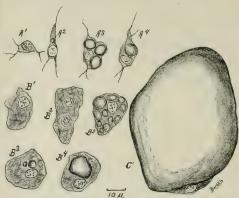

Fig. 2.—Developing and fully formed fat cells and the two types of cell from which fat cells originate. A<sup>1</sup> to A<sup>4</sup>, development from the so-called connective-tissue-cell form; B<sup>1</sup> to B<sup>2</sup>, development from the gland-cell form; B<sup>2</sup>, gland-cell form with two nuclei preparatory to cell division; A<sup>2</sup> to A<sup>4</sup>, B<sup>3</sup> to B<sup>5</sup>, cells with single and multiple deposits of fat; C, fully developed fat cell. All drawn to same scale with Zeiss's 2-millimetre oil-immersion apochromatic objective and Abbé's camera lucida.

The fat cell is developed into this form from a cell entirely free from fat. The fat is secreted in the cell in gradually increasing quantity by the metabolic action of the cell until the nucleus is displaced laterally by the increasing fat and the distended cell assumes a nearly globular form. But while this is the form of the fully developed cell during nutritive activity in the body of a well-nourished vertebrate, its original fat-free form is very different. What the original form is can not be said to be definitely settled. Observers who maintain for it a connective-tissue origin have described and figured it both as a branched and as an unbranched cell, and have described it as arising from the formed and from the granular unbranched cells of that tissue; others have described it as arising from lymphoid or special plasma cells. Where such diversity of opinion exists, it is obvious that there is opportunity for further investigation; and it is equally obvious that the real origin and original form of the cell must be known before its histological and physiological position can be accurately assigned.

The results of my investigations upon these disputed points are contained in this article, and, as regards the origin and original form of the fat cell, may be formulated as follows:

- That in the lower vertebrates the fat cell is developed from one form of cell, and that cells of this form are developed from special centers in the embryo.
- 2. That in the higher vertebrates fat cells are developed from two forms of cells differing greatly in size and shape.
- That one of the original fat-cell forms in the higher vertebrates is homologous with the special-center forms of the lower vertebrates; that this form of cell is gland-like;

that it in no way resembles the connective-tissue cell; and that the other form, while closely resembling the connectivetissue cell, is most probably a special cell, derived from the special-center form by cell division and migration.

If the fat bodies of an adult summer frog are examined, the fat cells will be found to present all the characteristics of the fully developed fat cell; but if the fat bodies of a winter frog which has used up most of its stored-up fat are examined, the cells will present a very different appearance. A section of such a body will show a collection of cells, some of which still contain more or less fat, while others are entirely free from it.

Those free from fat closely resemble the liver cells of the same animal. Between the closely packed fat-free cells nothing is visible but thin-walled blood vessels. Fat bodies of almost identical appearance are found beneath the skin of fotal higher vertebrates. The panniculus adiposus and the fat about the kidneys of mammals have their origin in such bodies. They are seen as rather regularly shaped, gland-like masses, and may be easily found and studied in the fetal cat at term.

Those beneath the skin first appear on the ventral surface of the body, in the axilla and groin, the regions to which subcutaneous fat is limited in certain of the lower vertebrates.

It will be seen from this that the fœtâl cat resembles the adult toad, for both have fat glands in close relation with the kidneys and localized beneath the skin on the ventral surface of the body near the limbs; and that this is in strict accordance with the rule that the fœtal forms of the higher vertebrates resemble the adult forms of the lower.

Fig. 3, from a photomicrograph of a section through the skin of a kitten at term, shows the gland-like masses of fat cells beneath the skin, and Fig. 4 shows distinctly the gland-like form of these cell accumulations. The cells composing these masses are irregularly polyhedral in form and of large size, being from  $15\,\mu$  to  $20\,\mu$  in diameter (Fig. 2, B<sup>1</sup> to B<sup>3</sup>, and Fig. 5). The nucleus, which measures about  $7\,\mu$ , is central, or nearly so, and in many cells can be seen to be in active caryocinesis preparatory to cell division (Fig. 2, B<sup>2</sup>). The growth of the masses is by means of indirect cell division, the development of the capillaries going on coincidently with that of the cells, as is the case in all gland development.

In the masses the cells will be seen to be in many different degrees of fat accumulation, some entirely without fat, others containing many fat droplets still separated from each other by intervening cell protoplasm, while in others the fat drops have coalesced into one and the cell nucleus has been more or less displaced laterally.

How utterly unlike these cells are to connective-tissue cells is fully shown in Fig. 5 (from a photomicrograph) and in Fig. 2, B' to B's, drawn with Abbé's camera lucida from the young developing cells of the fat bodies. The central cell in Fig. 5 is a typical fat cell of the gland-cell form before fat formation has commenced. As the focus, when the photomicrograph was taken, was adjusted to give a critical image of this cell, the neighboring cells are somewhat blurred from the objective not being perfectly aplanatic,

but it may be seen that they have the same general form and that some of them contain small fat drops. The existence of this distinctive gland-cell form of young fat tissue can be easily demonstrated upon any fœtal mammal of suitable age.

So far as I have been able to determine, this origin of fat cells from gland-like cells in gland-like masses occurs only in the lower vertebrates and in the fatal forms of the higher. In the lower vertebrates it is the only way by which fat tissue originates. In the higher vertebrates, while its first appearance is in special centers with these gland-like cells, a secondary origin also obtains. Undoubtedly it is this origin which has given rise to the theory of the connective-tissue origin of the fat cells, for the cells from which fat cells secondarily originate, before any fat is deposited in them, closely resemble connective-tissue cells. But, notwithstanding this resemblance, it is probable that they are cells formed by cell division from the original special-center cells, and that they, by cell migration, form metastatic fat masses in places where fat tissue does not occur in the lower vertebrate types. It is from this secondary form of migrated embryonal fat cell that all fat tissue outside the special-center masses is developed. In this way originates the fat tissue of the omentum and mesentery, that between the muscular layers, and in the many other parts of the body where it appears after or late in fœtal life.

The method of development is for a few of these secondary fat-cell forms to appear in the connective-tissue spaces alongside an already formed blood vessel. A capillary loop develops around these cells, other fat cells form outside this loop, another loop forms inclosing these, and so on, until a more or less distinct lobule of adipose tissue is formed. As it is by this process that new and scattered fat formations occur in the higher vertebrates after birth, it is the one most commonly and easily seen, and has, therefore, been generally considered the sole method by which fat tissue originates. It may be fairly well studied in the broad ligament of pregnant mammals; and if such studies were exclusively relied upon, an observer might well consider the connective-tissue origin of fat tissue established. But, like many other disputed questions in histology, the facts of embryology and comparative anatomy must be ascertained before right conclusions can be reached. If we examine a fœtus of right age, or a lower vertebrate, fat cells, forming in special centers from large polyedral cells only, will be seen; while if we examine an older fœtus of a higher vertebrate, the secondary method will be seen going on, together with the original method. For instance, if a section of the skin of a feetal cat at term is made through the subcutaneous fat masses in the groin or axilla, as in Fig. 3, in addition to the gland-like cell masses, cells will be found close to the hair roots and capillaries in the bodies of which fat is being deposited. These cells closely resemble connective-tissue cells and are the second form from which fat cells are developed in higher vertebrates (Fig. 2, A1 to A4, and Fig. 6).

These cells are much smaller than the special-center forms and of a different shape. They are from 12  $\mu$  to 20  $\mu$ 

long, but are only a little wider than their nucleus, which, like that of the special-center forms, is about 7 µ in diameter. Fat first appears in the cell in one or more minute drops, generally not more than three. As these fat drops increase in size the cell protoplasm (spongioplasm) between them gives way, they run together, forming a single drop which increases in size and displaces the nucleus laterally until the usual form of the fully developed fat cell is obtained (Fig. 2, C). When young-i. e., when fat first appears in them-these cells have processes similar to those of the formed (fixed) connective-tissue cells, though some observers have described them as having none. Had they none, their dissimilarity to connective-tissue cells would be more marked, but processes are always present by the time the cell has become stationary and fat formation has begun. The seeming absence of processes is due to the difficulty of so staining them that they and their connections to particular cells can be plainly made out. They are best shown in thin sections from tissue hardened in Müller's fluid or osmic-acid solutions and imbedded in paraffin, the sections fastened to the slide and deeply stained with Weigert's hæmatoxylin. The sections should be fixed to the slide without cement, otherwise the cement might become stained, so, possibly, giving erroneous pictures. To fix the section properly, a slide is cleaned with a solution of caustic potash to insure freedom from any trace of grease, a drop of water is then put on the slide, the section placed on the water, and the slide placed in the oven of a water bath at 42° C. until all wrinkles have disappeared from the section. The water is then drained off, bringing the section into close contact with the slide, and the slide is then replaced in the oven and kept there at the same temperature as before for twelve hours. The albumin of the section will so fix it to the slide that it may be cleaned of the paraffin and stained in the usual way.

Fig. 6, from a photomicrograph of a section so treated, shows one of the secondary forms from which fat cells develop. Similar cells are found wherever adipose tissue is developing outside the special-center cell masses. Comparison of the cell shown in Fig. 5 with the one shown in Fig. 6 will show most plainly the difference between the two kinds of cells from which fat cells originate. In comparing these figures it must be noted that the amplifications are different, the relative size of the cells being shown in Fig. 2, A' and B', where they are drawn to the same scale.

So far as the first, or gland-cell form, of the fat cell is concerned, there can be no question as to its entire dissimilarity to the connective-tissue cell; but, as regards the second or metastatic form, it is so similar in form to certain cells of the connective tissue that absolute proof that it is not such a cell is difficult and must rest at present upon the circumstances connected with its first appearance and upon its subsequent function. I have already stated that this second form probably arises by cell division from the first form, and by migration forms new centers for fat-tissue formation. As fat cells are specialized cells, having special and important metabolic functions to perform, and as their original forms are developed from special cells, both in the lower vertebrates and in the embryos of the

higher, it is natural to infer that all fat-cell forms have a similar origin. All special tissues arise from embryonal tissues by gradual differentiation, and when they have once reached a highly specialized form, change of form and function does not normally occur. Between cells having metabolic functions and those having supporting functions there is a wide difference, and, with the exception of the fat cell, it is generally considered established that cells having anabolic and catabolic action in nutritive processes do not change their functional form during development. If fat tissue is an exception to this general rule, it is certainly a curious anomaly.

Physiologists have fully demonstrated that fat is formed by the fat cells from substances other than ingested fat. The importance of this physiological action of the fat cells is emphasized by the great vascularity of adipose tissue, which shows that it is an active tissue physiologically; so that, both by its function and its blood supply, it closely resembles the glandular tissues. These facts are of much more importance when considering its true histological and physiological position than is the absence of excretory ducts, for in all these particulars adipose tissue is very like the liver as regards the glycogenic function of that gland. The liver forms glycogen from substances other than ingested sugar and gives it to the organism either as glycogen or in different form. In this function the liver is a ductless gland; the blood-vessels supply the cells with the material for metabolic change and carry away the product formed and given out. In like manner adipose tissue is supplied by its network of capillaries. Not only does the fat cell form fat, but it afterward disposes of it. Although the fully developed fat cell is so distended with fat that its protoplasm is reduced to a thin covering for the fat, it is still functionally active, and is not only capable of forming fat, but it returns the formed fat to the blood either as fat or in some other form. This inverse action requires fully as special metabolic function and activity as is required for the formation of the fat, for according to the varying demands of the system, so must the various fat cells give out the proper supply. In hibernating animals during the hibernating period, the consumption of fat and the consequent inverse metabolic action of the fat cells must be very carefully adjusted to the requirements of the body and to the length of the hibernating period.

The slow physiological giving out of fat is the true fatreducing method and differs from starvation in that the latter is an entirely pathological process. It is stated by some observers that the fat cells of a starved animal return to a connective-tissue form. This is undoubtedly an erroneous interpretation of structure. I have never been able to obtain the adipose tissue of a hibernating higher vertebrate during the hibernating period for examination, but in the frog the cells of the corpora adiposa never become connective-tissue cells. As the fat gradually disappears from them during the winter months, they gradually return to their original cell form. In this they closely resemble liver cells, for fat is often found in the latter; and when discharged, the cells return to their former shape. In starvation, however, the case is different. Then the fat is so rapidly given out by the distended adipose cells and their own nutrition is at the same time so interfered with that they have no opportunity to return to their original form. The cell walls fall toward each other like the walls of an emptied bag and in sections of tissue give an appearance much like that of connective-tissue fibers. But the cells have not become connective-tissue cells; they are only the shrunken and wrinkled, pathologically changed, fat cells. All the fat does not disappear from all the cells, even in extreme emaciation, and those cells devoid of fat still contain a yellowish fluid whose color is derived from the discharged fat. That they retain the coloring matter of the fat while they discharge the fat itself is entirely at variance with the supposition that they become connective-tissue cells.

Finally, if nutrition is resumed in a previously starved animal, all the fat cells again fill with fat without going through the process of development characteristic of their original development, and which would have been necessary had they assumed a connective-tissue-cell form.

We have the following, therefore, in support of the special cell origin and glandular nature of the fat cell:

- 1. Its occurrence in the lower vertebrates in special organs, composed of gland-like cells, developed from special centers.
- 2. Its first appearance in fœtal higher vertebrates in gland-like masses, developed from special centers, homologous with the special fat organs of the lower vertebrates.
- 3. The continuance of adipose tissue in the lower vertebrates as fat glands, never changing into other tissue, and as distinct in structure and function as other ductless gland
- 4. The limits placed upon the place of occurrence of adipose tissue in all animals, and its non-appearance in certain regions where connective tissue is always present.
- 5. Its specialized metabolic functions, and the glandlike development and arrangement of its blood supply, all of which place it in an entirely different histological and physiological class from that of the supporting functioned connective tissues.

Bibliography. - The bibliography is extensive, and up to 1887 is collected in a paper by Gage: Fat Cells and Connectivetissue Corpuscles of Necturus (Menobranchus), published in the Proceedings of the American Society of Microscopists, vol. iv, for that year. Of later date, Foster's Physiology, 5th edition, part ii, gives a most excellent account of the physiology of fat tissue; and Schäfer, in Quain's Anatomy, tenth edition, vol. i, part ii, gives a full account of the origin of the fat cell according to the connective-tissue cell theory.

## TENOTOMY FOR CONTRACTED TENDONS FOLLOWING INFANTILE PARALYSIS.

A REPORT OF A CASE.

By A. M. PHELPS, M. D.,

PROFESSOR OF ORTHOPÆLIC SURGERY IN THE UNIVERSITY OF NEW YORK AND THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL PROFESSOR OF SUKGERY IN THE UNIVERSITY OF VERMONT; PRESIDENT OF THE AMERICAN ORTHOPEDIC ASSOCIATION; SURGEON TO THE CITY HOSPITAL

VIVIAN M. C., a boy thirteen years of age, was born in London, and while an infant he was afflicted with infantile paralysis. The mother consulted several surgeons, and finally Mr.

Adams, in London. Mr. Adams had made for him his modification of Scarpa's shoe. He had been subjected to various methods of treatment from the time he was a child. The parent coming to this country, he was referred by Mr. Adams to a distinguished orthopædic surgeon of this city, who treated him for a year with massage. At the end of seven months a photograph was taken (see Fig. 1) which, as the boy expresses it, shows "the best possible position in which he could place his feet," The dotted lines show that the feet could not be placed at right angles. The mother then consulted a well-known conservative orthopædist of this city, who advised her to do nothing, but to build up his physical condition. She then consulted another orthopædist of this city, who informed her that by interrupted traction with his machine for one or two years he thought he could cure the deformity. The mother then consulted me on September 23d, and I informed her that I believed tenotomy of the tendo Achillis should be performed. The feet could not be placed at right angles with force at that time, and he was

F16. 1.

suffering from partial paralysis which had resulted in a shortening of the tendo Achillis which drew up the heel, producing a mild form of equinus. As he walked, the tendency was to throw the feet inward, and before many months he would have developed a severe double talipes varo equinus. When he came to this country there was placed a very severe injunction on the mother to "allow no American surgeon to operate on his tendons, else his feet would surely be ruined."

On September 25, 1892, assisted by Dr. Plimpton and Dr. Goodwin, and in the presence of Dr. A. J. Steele, of St. Louis, I performed the operation, and immediately placed the feet in a supercorrected position. They were kept in this position for six weeks, and were again put in plaster for two or three weeks more. He was allowed to walk with plaster of Paris until braces were adjusted. The tendons were lengthened two inches and a half, and on examination I think it will be difficult to determine where the new tendons begin and the old end.

In performing tenotomy on these tendons I inserted the tenotome, split the tendon an inch and a half subcutaneously, and then cut out on either side of the tendon above and below, allowing it to slip by and lap. This operation I had resorted to a great many times before, and, so far as I know, am the first to perform it subcutaneously. The case was presented at the Academy of Medicine last fall soon after the operation. At the

Fig. 2.

last Academy meeting, in October, 1893, I again presented him. He wore his braces only about three months from the time of the operation; then they were found no longer necessary. On

Fig. 3.

presenting him before the Academy of Medicine, it was found that he walked almost perfectly, that there was no tendency to relapse, and that he could stand upon his toes, as seen in Fig. 2, and could place both feet beyond a right angle, as seen in Fig. 3.

My conclusions are that in these cases of contracted tendons following infantile paralysis much better and more rapid results can be attained by subcutaneous tenotomy than by all the bracing known to the orthopædic world. After these tendons have been lengthened, if then braces

are required, the orthopædist can adjust them, and well he should. The constant pulling and hauling of such tendons with traction machines or braces is to my mind a most unscientific procedure, and should not be tolerated by any patient.

# SOME CRITICAL AND DESULTORY REMARKS ON RECENT LARYNGOLOGICAL AND RHINOLOGICAL LITERATURE.

By JONATHAN WRIGHT, M.D.,

PROFESSOR B. FRAENKEL has recently launched a new laryngological and rhinological journal on the already over-crowded sea of special medical literature.

If succeeding numbers equal the first two in the merit of their contents and the pre-eminence of their contributors, the Archiv für Laryngologie und Rhinologie, if it finds no "long-felt want to fill," will at least earn for itself a foremost place among the numerous journals especially devoted to the diseases of the nose and throat.

The opening contribution to the first number, continued in the second, is from the pen of the distinguished editor himself, detailing the results of his Studies in the Microscopic Anatomy of the Larynx. With the help of a series of fine photographs, he seems to have conclusively proved the presence of glands in the immediate vicinity of the vocal cord, an assertion which he had previously made in communications published elsewhere.

He includes in the term vocal cord all the tissue which projects beyond a plane even with the tracheal wall and the lateral ventricular wall. It would be fortunate if every writer would specify exactly what he means by vocal cord, or, better still, if some exact limitation to the term were generally agreed upon.

Fraenkel found the opening of one of the glands 1.8 millimetre from the edge of the cord, but he quotes Coyne as having found them nearer.

"One gets the impression," Fraenkel says, "on examining the anatomical preparations, that muscular contraction would press out the glandular secretions."

In some of his former papers Fraenkel has stated that papillæ are found in the normal laryngeal mucous membrane in places.

As this has a direct bearing upon the accuracy of the clinical observation, frequently questioned, of mucous patches in the larynx of syphilitics, his present explanation, if rightly understood, is somewhat disappointing. He says that below the free edge of the vocal cords there are folds of squamous epithelium running parallel with them. These folds (*Leisten*) he calls papillæ, because on transverse section (vertical as to the body) they have that appearance, but they are not seen on horizontal section (parallel with the cords).

Now, a true papilla is, of course, seen in sections made in any plane, and, from the perusal of Fraenkel's work, it is impossible to understand exactly whether he has found the true papillæ in the larynx or not. Pathologically, the folds are produced from the same cause as papillomatairritation, the products of chronic inflammation.

Unfortunately, Hopman and his followers have produced similar confusion in nasal pathology.

The lymph nodes shown by Fraenkel suggest the probability of the occurrence of lymphoid hypertrophy in the larynx. Very few cases have been reported. One was reported by me in the Journal of the American Medical Association, September 26, 1891, when the remark was made that, in all probability, the apparent rarity was really due to insufficient microscopic discrimination, since clinically they may closely resemble papillomata.

He emphasizes the statement that the appendix of the laryngeal ventricle is really a separate organ, communicating with the latter by a comparatively narrow fissure. He criticises the method of demonstration adopted by Gerlach, who filled out the ventricles and their annexa with absorbent cotton saturated with warm paraffin, and, allowing it to harden, from the mold thus obtained described their normal shape. Fraenkel justly says this only shows the extent and direction to which the cavities may be stretched. He, however, maintains, with less show of reason, that serial sections represent the normal condition better. A collapsed laryngeal ventricle, post mortem, probably shows as little of the true intra-vitam condition as does the collapsed lung. Neither the artificial dilatation nor the post-mortem collapse can be reasonably regarded as representing the natural condition. It is more reasonable to suppose that a form midway between them is the one more nearly approached to the one assumed during function. The arrangement of the muscular fibers would suggest dilatation during the production of loud vocal sounds.

From these considerations, therefore, and from certain anatomical conditions of the larynx in lower animals, it seems to me we can not be so sure as Fraenkel appears to be that the appendix ventriculi larvngis has nothing to do with the vocal sounds, and that "the only function in accordance with the construction of the appendix is that ascribed to it by Morgagni-viz., to secrete a fluid which is intended to keep the vocal cords lubricated." The results obtained in a case of total extirpation of the larynx, and reported by Wolf in the Berliner klinische Wochenschrift, No. 42, 1893, seem to indicate, however, that vocal sound production, at least Helmholtz's "ground-tone" part of it, is much more simple than usually supposed. By means of a slight modification of his artificial larynx, Wolf obtained from the patient a voice hardly noticeable in its variation from the former normal condition. Of course, an artificial larynx does not allow for the changes in shape and position supposed to be so necessary for anything like normal sound production.

Fraenkel's photographs of the sections of the larynx require considerable study before their meaning is apparent; but with his very lucid explanations they are very instructive. The abundance of the mucous glands is very striking, for in places they are as numerous as they are in the nose.

He again calls attention to the patches of pavement epithelium found here and there in the larynx elsewhere than on the cords. He mentions the digitations of these

flat cells, reaching into the stroma at the posterior commissure, and the islands of epithelium in the sections due to the transverse divisions of these digitations.

These anatomical relations are well known to histologists, but it is well to bear them in mind in clinical work, in order to appreciate the elements of uncertainty that may enter into the diagnosis of doubtful neoplasms by the microscope.

The question of the transformation of benign into malignant growths will never be settled by citation of cases. The further evolution of biological and pathological laws alone can do it. As far, however, as clinical evidence, supported by histological examination, can go, E. Fink, in Fraenkel's Archiv, No. 2, has narrated a case in which there was an apparent transformation of a benign growth of the antrum of Highmore into a malignant tumor. Edematous polypi had existed for years in the nose and in the antrum. They were examined microscopically and found to be benign. Suddenly evidences of malignancy appeared in the antrum. The man shortly died of a cancer having its origin there.

While we may admit the possibility of the growth having begun in the polypi, two objections on the spur of the moment may be advanced:

- 1. Œdematous polypi of the nose do not fall under the usual definition of a tumor as "a circumscribed new formation of tissue, not due to inflammation, and not fulfilling any physiological purpose, but existing as a more or less independent structure." There is abundant authority for the assertion that the ordinary nasal polypus is due to inflammation, and does not "exist as a more or less independent structure." It is not usually a true myxoma.
- 2. The writer has only shown that a malignant growth occurred in the immediate vicinity of a pre existing benign one, not that it had its *origin* in the benign growth itself.

The inference in this case, as in many others, is very strong, but, in the face of pathological laws as usually accepted at present, it is *proof*, not inference, we want.

In the first number of the Archiv Sokolowski describes an interesting case under the title of A Contribution to the Question of the Possibility of the Transformation of a Benign Laryngeal Tumor into a Malignant.

As is well known, Semon, of London, shortly after the tragic death of the Emperor Frederick, collected the data of a large number of cases of laryngeal neoplasms. The result of a very exhaustive consideration of these cases was that such a transformation is of the greatest rarity. It seemed probable in five cases out of 8,216 that such a transformation had taken place. The evidence of such a change in nearly all the cases reported is unsatisfactory. Still, in an inexact science, where all things are possible, the occurrence of such a metamorphosis can not be denied as a possibility, however much we may be disposed to disbelieve it in any given case.

One fact, however, stands pre-eminent, and that is the unreliability of differential diagnosis from either purely clinical or purely histological data. This is well exemplified in Sokolowski's case. A polyp was removed from the left vocal cord under the impression that it was benign; it was preserved, but not examined histologically. Four years later there was a recurrence at the former site. This was destroyed with the cautery, although it was then supposed to be malignant. Eight months later the patient was operated on by another laryngologist, who, in view of the history and the appearance of the growth, clinically and histologically thought that it was a benign adenoma. Then Sokolowski examined the piece he had taken out five years previously and concluded that it was an adeno-carcinoma. This was afterward proved to be the case, the growth again recurring in a form clinically plainly malignant.

Curiously enough, Krieg, in the second number of the Archiv, reports another case of glandular carcinoma lasting for six years and a half, operated on three times by endolaryngeal methods, the patient being still alive and well. These cases also tend to strengthen the position taken and still held by Fraenkel as to the preference of endolaryngeal over extralaryngeal methods in certain cases of malignant disease.

As time goes on those of us who have reproached ourselves with unfavorable results in the surgery of the accessory cavities of the nose may take a little courage at the confessions of more recent writers on the subject of intranasal suppuration.

Many papers have been published in the last two or three years detailing very satisfactory results in operations for empyema of the antrum and of the other accessory sinuses.

The large number of cases reported by single observers, the remarkable proportion of cures, and the short duration of treatment have prevented many from considering their own clinical experiences of value, limited as they are in numbers and discouraging in results. Grünwald's recent monograph, Die Lehre von der Naseneiterung, and Jansen's Zur Eröftnung der Nebenböhle der Nase, etc., in Fraenkel's Archiveno. 2, except in the number of cases, conform more to my own experience. To sum it all up—for this is no place for the complete review these excellent papers deserve—the exact diagnosis is often extremely difficult; in old cases extensive openings of the sinuses, curetting and packing, and long after-treatment, are usually necessary; the prognosis is doubtful; the length of treatment discouraging to patient and operator.

Zwaardemaker, in the Archiv No. 2, speaks of the value of the film made by the breath in expiration on a cold mirror held beneath the nostrils in the diagnosis of nasal obstruction—the stenosed nostril showing a smaller area. This is a very interesting suggestion. There is nothing more unreliable and puzzling than a patient's statement in regard to respiration through his nose. It is frequently very difficult even on inspection to estimate the actual size of the breathway, for a tortuous passage does not necessarily mean a stenosed one. There is a fallacy, however, in the author's method, which in some cases may be a very

great one. The chief pathogenic importance of nasal obstruction is felt in inspiration, not expiration. The action of the alæ nasi and of the soft palate, and doubtless that of the intranasal structures themselves, bear very different relations to impeding the air current in inspiration and in expiration.

Nevertheless, this attractive and, as far as I know, new method of estimating a frequently puzzling condition may be found by more extended observation to possess considerable diagnostic value.

To me about the most interesting of all the papers in the two numbers of the Archiv für Laryngol., etc., is the one by Franke on the Experimental Investigation concerning Air Pressure, Air Currents, and Air Diffusion in the Nose and its Accessory Cavities. The works of Donders, Bloch, Paulsen, and others are unsatisfactory, because in many particulars they did not conform to expectations derived from our knowledge of the laws of physics and our acquaintance with intranasal anatomy, while deductions which would inevitably follow some of their statements are not borne out in the clinical experience of morbid processes.

It appears to me that Franke's work is much more accurate in its methods and more reasonable in its results. Space does not allow an adequate description of this valuable paper, but the three devices he experimented with may be described as follows:

1. Nose Tubes.—The nasal chambers were represented by two glass tubes ten centimetres long and fifteen millimetres in caliber. A glass bulb three centimeters in diameter, which was fixed to the side of one of the tubes, communicated with it by an opening of five millimetres and represented the maxillary sinus and its orifice. To the side of the other glass tube, as well as to the glass bulb, supplementary tubes were adjusted for the use of a manometer.

If now these glass tubes are fitted air-tight into the nostrils, that end of the tube will represent the artificial choana, while the free end will represent the artificial nostrils.

"By the following modifications, we may produce partial or total nasal stenosis. I had made eight olive-shaped, hard rubber balls, of which four were eight millimetres and four were three millimetres in diameter. By placing these balls here and there in the lumina of the glass tubes, we may observe the air-pressure phenomena in the nasal and maxillary cavities as they occur in different cases of well-marked nasal stenosis."

2. Nose Model.—"In order to establish the influence which the form of the nasal cavities has upon the variations of the air pressure, and in order to measure the air pressure in the accessory cavities, I had prepared, as a nose model, a small flat box which had about the shape and size of the nasal cavities, and had adjoining compartments to represent the frontal and sphenoidal sinuses; the external nasal wall and the nasal sæptum were formed by plates of glass. The frontal and sphenoidal sinuses are in communication with the nasal chambers through openings. One of the glass plates was also pierced and an entrance made to the maxillary sinus, which was represented by gluing on half a

medicine glass. Openings in the sides of the different cavities allowed a communication with a manometer."

3. "For the necessary investigation of the natural respiratory cavities I prepared a fresh head in the following manner.

"The head, which was normal and from a female subject of twenty-five years, was sawed through exactly in the median plane; the remains of the sæptum were removed, so that the nasal, frontal, and sphenoid cavities lay free. The maxillary sinuses also were exposed by a sagittal cut 4.5 centimetres from the median plane. After I had assured myself of the permeability of the openings leading to the accessory cavities, the mucous membrane was stained black with ink, and on the cut surfaces two glass plates were fastened air-tight." (He used tobacco smoke to show the direction and shape of the air currents.) "The cavities were bored into from without, for the use of a manometer."

By these three ingenious arrangements he obtained uniform results which are very interesting and apparently reliable. From the results thus experimentally obtained he drew various conclusions, some of which are as follows:

- "The air pressure in the accessory cavities is the same as that of the cavity into which they open. . . .
- "The amount of air pressure in the nose is determined-
  - "1. By the actual size of all the nasal cavities.
- "2. By the relative size-i. e., by the difference in size between the choana and the anterior openings (or any other narrowest passage).
- "3. By the situation of the narrowest place in the nasal passages.
- "4. By the force and rapidity of the respiratory move-
- "The air pressure in the normal nose and accessory cavities in normal breathing is at most two to three millimetres of water. This amount is, of course, insignificant. . . .
- "Difference in air pressure stands in no causative relation to the variation in size and shape of the nasal and accessory cavities. . . .
- "It is a mistake from a physiological standpoint to distinguish between a respiratory and an olfactory region, for the olfactory region is the true respiratory region. The nose fulfills its function as the organ of smell in virtue of the fact that the chief air current in inspiration passes over the distribution of the olfactory nerve.

"The terrace-like arrangement of the turbinated bones, hanging one over the other, and the peculiar anatomical structure of the nose, which permits of eddying currents, and the eddies caused by the meeting of the currents of inspiration, also serve to bring the air thoroughly and extensively in contact with the olfactory nerve distribution. . . .

"The change of air takes place more quickly in the accessory cavities; the larger the communicating openings are, the more propitiously the latter lie to the passing air current, and the stronger the respiration is. . . .

"The accessory cavities can serve neither for moistening nor warming the air, nor, as Braune and Clasen would have it, to increase the sharpness of smell.

appropriate arrangements, but the accessory cavities have no function at all. Since these accessory cavities are without function and have nothing to do with respiration, their size and development are as independent of the different respiratory processes as is the size of the nasal cavities of the amount of air pressure."

Franke does not seem to have in mind any modification of vocal sound produced by the accessory cavities, nor the lightness and strength they add to the bones of the head, but refers only to the more prominent of the intranasal functions.

The case, narrated by Dr. Grayson in the Medical News of November 4, 1893, p. 520, of spontaneous healing of an ulcerative tuberculous laryngitis attracts attention because of the bearing it has upon remedial measures in this terrible disease. One can not but be impressed, on reading Heryng's last paper in the Journal of Laryngology and Rhinology (Nos. 8 and 9 of 1893), as well as his other previous communications, with the sincerity and trustworthiness of his statements of fact. He has demonstrated, without a doubt, the possibility of a cure of laryngeal phthisis, and for the demonstration he deserves and will receive credit from laryngologists the world over. By curetting the ulcerations and rubbing in lactic acid, he has cured a very few patients (sixteen cases thus far reported) who have been free from the laryngeal disease for periods of five to two years up to date. But Dr. Heryng has seen eight hundred and thirty-eight cases and treated surgically two hundred and thirty-nine. Presumably, then, not one third of the cases were amenable to treatment. Of the cases treated, about one in eighteen was cured; and of all the cases seen, one in fifty-two. This being the most favorable of all trustworthy reports, after making proper allowance for possible errors due to the enthusiasm of the author, for possible errors of diagnosis, or of observation, we are unavoidably a little discouraged at the showing. Dr. Heryng himself admits the occurrence of spontaneous healing. He instances a very convincing case. Dr. Grayson's case, referred to above, is not so convincing. Syphilis as a concomitant factor was not entirely ruled out. Spontaneous cure does not in all probability result once in eighteen times. Whether it does not occur once in fifty times is extremely doubtful. That is the discouraging aspect of the question from a clinical standpoint. Theoretically, does it seem possible that an open wound in the larynx, constantly bathed in sputum full of bacilli from the lungs-even supposing, for argument's sake, that the diseased area has been eradicated by curette and aciddoes it seem probable that such an open wound would often heal without reinfection?

Operations on the joints are not analogous cases at all. They could only be made analogous by using dressings of tuberculous sputum for the wound.

We can not fail to admire Dr. Heryng's courage of conviction, but we can not share it.

C. Stoerk, in the Archiv No. 2, lets off a blast of "The nasal cavities have for their different functions indignation and puts some common sense into forcible words on the subject of the creasote therapy of tuber-culosis.

"I have no intention," he says, "of provoking a controversy, but I feel myself forced to the expression of my opinion of creasote medication by the enormous number of constantly repeated cases which I see year in and year out in my outdoor clinic, as well as in my private practice. Half-dying people lay before us their crumpled prescriptions, with their solitary constituent of creasote, and still creasote in the most varied forms, and from their history it is learned that since they have used this medication they have entirely lost their appetite and, the taking of nourishment sunk to a minimum, having lost frightfully in weight, reduced to a skeleton, plagued every hour of the day with cough and night sweats, they have dragged out a miserable existence. 'I can not get the disgusting creasote taste out of my mouth' is their typical complaint. The drug, however, they continue to take, because they have heard of so many who have been cured of tuberculosis by creasote; in their delirium of hope the unfortunates cling to a straw, and their faith in the specific is unconquerable." Perhaps his warmth is a little unscientific, but those whose cardiac plexus is in a healthy state will overlook the non-judicial tone of his remarks, especially those who, like myself, in chasing the ignis fatuus of tuberculosis therapy, once wrote many such prescriptions and have seen many more and their results.

The statements of Seiler, in the last edition of his work on the throat, under the head of Uterine Reflex Laryngitis, must certainly have produced considerable skeptical astonishment in many laryngologists.

In the second number of the new Italian journal Archivio italiano di otologia, rinologia e laringologia, Fereri has an article on Laryngeal Neurosis after Certain Gynæcological Operations.

He insists on the clinical association of hysterical aphonia and certain isolated paralyses of the laryngeal muscles with various malpositions of the uterus and diseases of the uterus and the annexa.

The ætiological connection is signalized in these cases by the cessation of the laryngeal symptoms on the correction of the genital troubles. Both Seiler's and Fereri's observations are somewhat indefinitely stated. As the literature of the subject is so scanty, their statements, if not unreservedly accepted, are worthy of note, though we confess we are somewhat reluctant to seriously attempt to diagnosticate uterine displacements by means of the laryngoscope, the possibility of which is asserted by Seiler.

There have recently been published some interesting papers on diseases of the nasal sæptum, a structure which has been credited with considerable immunity from morbid processes.

In the Berliner klinische Wochenschrift, No. 46, 1893, we find a simultaneous report by two different observers of two cases of Idiopathic Acute Perichondritis of the Nasal Sæptum. Dr. Schröder and Dr. Lublinski, apparently independently of one another, each report a case. From

the statements made in these two articles there seem to have been only seven or eight cases, inclusive of their own, reported.

This is a rather remarkable showing, but it is still more noteworthy how extremely few cases of perichondritis from trauma are seen or reported when we consider what a prominent feature the triangular cartilage supports.

By perichondritis, however, we usually mean an inflammation leading to necrosis of the underlying cartilage. When we consider what a vascular supply the cartilage has from both sides, probably richer than any other cartilage in the body, the rarity of necrosis is comprehensible even in its exposed condition. It is probable that perichondritis and chondritis is the process to which we must ascribe many of the deviations, spurs, and thickenings of the nasal saptum; and these inflammations may be caused not only by trauma, but by extension from the mucous membrane in ordinary rhinitis.

Perforations of the sæptum due to syphilis and to the finger nail are common enough, but they belong to another category.

Chiari's paper in the Archiv f. Laryng., No. 2, on Tuberculoma of the Nasal Mucous Membrane adds nothing to the work done some time ago by Hajek, except the report of six new cases.

But Herzog, in the American Journal of the Medical Sciences for December, 1893, writes a very readable paper on Tuberculosis of the Nasal Membrane. In remarks preliminary to the report of cases he speaks of Hildebrandt's experiments, remarking that "the micro-organisms suspended in the air we breathe do not normally get into the deeper parts of the respiratory tract, but are kept back by the nose and naso-pharynx. It is evident that if these parts have the function of keeping back from the lungs pathogenic micro-organisms suspended in the air they must necessarily be endowed with such properties as to make innocuous or remove such micro-organisms."

In this connection I can not refrain from quoting from a paper of my own, written four or five years ago, which detailed various experiments in nasal bacteriology and was published in this *Journal*:

"It is yet an unsolved mystery how the Bacillus tuberculosis reaches the most frequently chosen seat of its selective action in the apices of the lungs, and how the pneumococcus usually reaches the lower lobes before pneumonia occurs. To a bacteriologist it is almost inconceivable how a microbe, entering the anterior nasal meatus with the tidal air, should go through the tortuous moist passage of the nose, past the broad surface of the palate, and the postpharyngeal wall, into the larynx, between the false and true cords, down the long tubes of the trachea and bronchi, and finally find a lodging place on the walls of the bronchioles and air cells. The chances of its being arrested before it reaches them seem almost infinite, especially since the tidal air must stop at a comparatively high point in the respiratory channel and flow upward again on expiration." It was found-perhaps from an insufficient number of experiments-that the nasal chambers in one case were "capable of filtering out about three fourths to four fifths of the bacterial contents of the air passing at the rate of one litre a minute, but we have about nine litres a minute passing through the nasal chambers." From this I drew the conclusion, tentatively, in view of the small number of experiments, that the nose does not in itself act as a perfectly efficient filter—probably far from it.

Feb. 24, 1894.]

The recent remarkable statements of Wurz and Lermoyez in the Annales des maladies de l'oreille, etc., August, 1893, apparently grounded on irreproachable experiments, are incomprehensible if we can give any credence to former work in nasal bacteriology. They maintain not only that the nasal mucus is sterile, but that it is a strong germicide. It annihilates the anthrax spores in broth when mixed with it. It is evident that somebody has made a mistake.

To return to Herzog's paper. He reports ten new cases of nasal tuberculosis of his own, some of which might more properly be termed lupus, while others were associated with lung tuberculosis. He tabulates eighty cases of tuberculosis of the nose hitherto reported. It may perhaps be well to remark here that tuberculosis of the nose in a patient dying with pulmonary or laryngeal phthisis is an incident that is easily, nay, is pretty sure to be, overlooked. It would inevitably be found, if all cases of pulmonary phthisis were examined rhinoscopically, that nasal tuberculosis coexists in many.

That Herzog has only been able to collect twenty cases of primary nasal tuberculosis is, however, instructive. Some cases have been reported, probably since Herzog wrote his paper, by Farlow (New York Medical Journal, November 4, 1893) and Chiari (loc. cit.).

The situation of the disease in the eighty cases tabulated, where it was definitely mentioned, was upon the cartilaginous sæptum in nearly all the cases—in some including the floor of the nose and the anterior end of the inferior turbinated. This choice of situation might indicate contamination from the finger nail, but not necessarily, since more dust, presumably more germs, lodge in the front of the nose.

Ulcers, too, may frequently exist far back and escape notice.

Dr. Herzog has, so far as I know, given us in this paper the best résumé of the subject of nasal tuberculosis in the English language, and perhaps of any yet published. He summarizes as follows:

"1. Tuberculosis of the nasal mucous membrane, compared with tuberculosis of other parts of the respiratory tract, preferably with this affection of the lungs and larynx, is a rare disease; it is, however, not as rare as formerly supposed.

"2. It is generally a secondary affection, but also occurs primarily, as proved by unmistakable clinical evidence and by post-mortem facts.

"3. Where it occurs it is frequently secondary to pulmonary and larvngeal phthisis.

"4. It occurs in the form of ulcerations, tumors, and a combination of both. The tumor is generally found in the primary cases, while the ulceration is the prominent factor in advanced cases of phthisis.

- "5. It may occur at any age (except probably in the very earliest months of life), preferably at the ages between ten and forty years.
  - "6. It does not show any predilection as to sex.
  - "7. Its seat is preferably the sæptum cartilagineum.
- "8. Its course is very chronic, and relapses after surgical interference are the rule.
- "9. It is, per se, not dangerous to life, but may eventually lead to fatal complications, such as basilar meningitis and possibly miliary tuberculosis.
- "10. One of its most important direct complications by continuity is that with tuberculosis of the naso-lacrymal duct and the conjunctiva.
- "11. It may also be complicated with tuberculosis of the pharynx, palate, tongue, external integument, lupus of the nose, face, tuberculosis of the cervical glands, empyema of the antrum of Highmore, etc.
- "12. Lupus of the face or of the nasal mucous membrane may, in its further development, lead to tuberculosis of the nasal mucous membrane" [sic].

# THE EFFECT UPON THE LUNGS OF EFFUSION INTO THE PLEURAL CAVITY.\*

BY EGBERT LE FEVRE, M. D.,

MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK:
ATTENDING PHYSICIAN, DEPARTMENT OF THE HEART AND LUNGS,
UNIVERSITY MEDICAL COLLEGE DISPENSARY:
CONSULTING PHYSICIAN TO BETH ISRAEL HOSPITAL, ETC.

In looking over the text-books on practice of medicine and diagnosis one is struck with the unanimity of the statements in regard to the effects that effusions into the pleural cavity have upon the contained lung, the heart, the intercostal spaces, and diaphragm and abdominal organs. The general idea conveyed is that the exudation gravitates to the most dependent portions of the pleural sac, and immediately exerts a positive pressure upon the diaphragm and thoracic wall, and forces the lower portion of the lung upward in direct proportion to the extent of the effusion. is also taught in most of the books that the upper surface of the fluid, when the patient is standing or sitting erect, is in a horizontal plane, and, when the position is changed, there is a corresponding change in the level of the fluid; in other words, it acts as fluid in an open vessel, always seeking a hydrostatic level. This explanation, while very simple, entirely ignores the physiological laws of respiration and takes no cognizance of the forces that are involved. What are these forces and their laws? As soon as the newborn child takes its first deep inspirations the lung is in a condition of distention the degree of which is different in different portions of the lung. The two surfaces of the pleura are in close apposition throughout their entire surface, and the lung is constantly striving to regain the condition of equilibrium. This it is prevented from doing on account of the resistance offered by the bony thorax and its muscles and the action of the diaphragm, although it is able to curve the diaphragm upward, depress the ribs, and

<sup>\*</sup> Read before the Society of the Alumni of Bellevue Hospital, January 3, 1894.

draw in the intercostal muscles. This suction power of the lungs is the so-called negative pressure of the physiologist. If a small incision is made through the intercostal muscles into the pleural sac, so that there is no obstruction to the entrance of air, then the elasticity of the lung quickly causes it to resume its normal form, according to the resilience of the tissues, and the lung is said to have collapsed, the atmospheric pressure being equal on both sides of the alveolar walls, the ribs, intercostal muscles, and diaphragm no longer opposing. Air entirely surrounds the lung and separates the two surfaces of the pleura.

When fluid is poured into the pleural cavity another factor comes into play, altering the condition of the lung.

Clinicians have repeatedly called attention to cases of pleurisy with effusion in which the line of flatness was not straight and did not readily change with the altered posture of the patient. These departures from the assumed typical line have been explained by many plausible theories.

Damorseau first discovered that the line of flatness was always a curved one when the lung on the affected side retained its normal elasticity. Ellis later emphasized the fact and accurately described the curve, so that to-day it is known as the curved line of Ellis, or the letter-S line.

Garland (Pneumonodynamics), in a series of experiments on dogs, by injections of cocoa butter into the pleural cavities, demonstrated, by the molds thus obtained, that this curved line was constant when the lung was normal and was formed by the action of the lung on the fluid, and not, as was generally supposed, by the fluid molding the lung. He found that "the fluid collects first in the complemental spaces. Thence it extends in a narrow band upward and forward between the lower border of the lung and costal attachment of the diaphragm. At the same time it spreads out in a thin sheet over the diaphragm. The fluid continued to proceed in this manner until it began to bag down the diaphragm, to obliterate the intercostal depressions, and to rise behind the lung in the vertebral groove, and, lastly, it appears between the lungs and the lateral chest wall."

These experiments were the first that accurately determined the line of the curve. They also proved our power to accurately map out the level of the fluid by percussion, as the line, so determined, was found on dissection to correspond in all points to the level of the cast.

The experiments on dogs demonstrated that the upper surface of the fluid was curved, but did not explain the

Garland used a modification of the well-known laboratory apparatus to illustrate the action of the lung on the fluid in the pleural sac and the forces involved.

A rubber balloon, with glass tube attached, is put in a bell jar with an opening for a rubber cork at the top and in the side. The tube attached to the balloon is carried through the cork at the top and left open; another rubber cork with glass tube attached closes the opening in the side of the jar. The bottom of the bell jar is closed with a rubber diaphragm. The air in the bell jar is exhausted through the opening in the side. When this is done, the rubber

points, the rubber diaphragm arching up and encircling the lower part of the balloon.

If a rubber tube, attached to the glass tube in the side of the jar, is immersed in water and opened, the retractile power of the balloon is sufficient to draw the water into the jar, when a small amount of water is allowed to enter. The balloon holds the water wrapped about its lower border, so to speak, by virtue of its negative pressure. "The column of water, instead of supporting the balloon, is actually suspended by the retractile force of the latter, and the column of water, being in suspension, must exert a negative pressure on the balloon in proportion to its weight." The balloon retains its convex shape. The rubber diaphragm is arched up, but to a less extent. The surface of the water is biconcave, and it is confined to the lower part of the jar. The balloon assumes its original shape when air is let into the jar, because air does not exert a negative pressure; but when water is used, the balloon retracts until its negative pressure or retractile power is equalized by the weight of the column of water it suspends. When this point is reached the diaphragm is no longer arched upward; it has resumed a straight line on account of the resilience of the rubber. If more water is forced into the jar, then the weight, being in excess of the retractile or suspending power of the balloon, will begin to exert a positive pressure on the diaphragm, bagging it down, while at the same time it has a negative pressure on the balloon, causing it to distend as the diaphragm is displaced downward. All excess of water introduced will so continue to act on the diaphragm and balloon until that point is reached beyond which the rubber diaphragm can not be carried down, at which it becomes a fixed point of support for the column of water. If more water is now forced into the jar the balloon will again begin to contract, not because the water is compressing it, but because the negative pressure of water is, to a certain extent, removed by the support of the diaphragm. The balloon flees before the advancing level of the fluid, but still exerting, with decreasing intensity, a negative pressure on the fluid, whose upper surface still retains a convex form. The balloon will so continue to act until its elasticity reaches the zero point and the balloon is in its normal condition-i. e., until it reaches the size it originally was before it was inflated. The fluid can not act on the balloon until the elasticity of the latter is exhausted. Beyond this point all the water introduced exerts a positive or compressing effect on the balloon until at last it is airless.

Instead of the distended balloon in the glass jar, let us consider the distended lung in the airtight thorax. The amount of distention of the normal lung during life is not as yet accurately determined. Foster, by fitting a manometer in the trachea of a cadaver and then opening the thorax, found the pressure to be about seven millimetres of mercury. This is far below that of life. In the balloon the degree of distention was the same throughout the lower segment, and consequently the level of the fluid was uniformly curved; but all portions of the lung are not equally distended, the distention being greatest in the lower segment, in balloon is in contact with the inner side of the jar at all the axillary region, less in the mammary, and least behind.

In pleurisy with effusion the fluid, if no other force acted upon it, would gravitate to the most dependent portion of the pleura and seek a hydrostatic level. But as the lungs contract with most force in the radii of its greatest distention, it is able to overcome or modify gravity and draw the fluid to that part, as was shown in the distribution of fluid in Garland's experiments, and the flatness on percussion will appear first in the axillary line. Portions of the lung will continue to draw the fluid until the distention is equal throughout; consequently the level of the fluid will rise higher at those points where the distention of the lung was the greatest.

As was explained in the experiment with the balloon and glass jar, the diaphragm is arched upward by the retractile power of the balloon; so in the thorax the lung acts upon the diaphragm to draw it up and upon the ribs to depress them, and diaphragm and thoracic wall are constantly trying to regain their normal or zero point of tension. As the weight of the fluid exerts a negative pressure on the lung, it relieves the diaphragm and thoracic wall of that amount of traction by the lung, and the one descends and the other expands, giving increased size to the affected side of the chest. The fluid can exert no positive pressure on the diaphragm or ribs until the weight of fluid exceeds the retractile or suspending power of the lungs; when it exceeds the amount, then the excess of weight bags down the diaphragm and produces a lateral pressure on the chest wall, but at the same time exerts a negative pressure on the lung, causing it to expand again. When the weight of the fluid has carried down the diaphragm and bulged the chest wall to the utmost, then the negative pressure of the fluid ceases to cause distention of the lung. As the amount of fluid increases, the lung retracts before the fluid, again exerting a suspending power, which decreases until the zero point of retraction is reached—that is, until it has reached the size it has when air is allowed to enter the pleural cavity freely. Rokitansky says the normal lung can contract to an eighth of the size it has when distended in the thorax. Until the zero point of contraction is reached, the fluid exerts no compression on the lung. "It merely flees before the fluid." All excess of fluid beyond this point begins to exert a positive compression of the lung.

Thus far the reaction of the healthy lung only has been considered. If the lung is bound down by adhesions or its resilience is diminished by pathological conditions—as emphysema, tubercular infiltration, etc.—then the fluid would not assume as marked a curve line; it would earlier exert a positive pressure on the diaphragm and chest wall and a compressing effect on the lung. This line has a positive diagnostic value, as its curve depends entirely on the elasticity of the lung. Although foreign to the subject, the effect of the fluid on the lung sheds some light on the relation that the occurrence of an effusion into the pleural cavity has upon tubercular disease in the lower lobe of the lung on that side, often changing an acute process into a chronic one, or even arresting it.

The fluid acts somewhat as a splint does to an inflamed tubercular joint, giving the part physiological rest and allowing nutritive changes to occur in the infected part.

Artificial withdrawal of the fluid in these cases not only removes this, but produces a traumatism. The effect of the effusion upon the opposite lung and the heart, together with the explanation of some of the symptoms and physical signs, while very interesting, are not germane to the discussion.

161 WEST TWENTY-THIRD STREET.

# NOTES ON TWO HUNDRED AND FIFTY CASES OF EPILEPSY.

By R. K. MACALESTER, M. D. (ZURICH).

(Concluded from page 108.)

Psychical Epilepsy.—Among the atypical and rarer forms of epilepsy that present paroxsymal psychical symptoms, a synopsis of the following cases will be sufficiently interesting to warrant a recital:

Case I.—E. G., aged twenty-seven years, born in Canada, married at the age of sixteen years.

For over a year past has had absent-minded spells, occurring about twice a week and lasting about twenty minutes. During one of these attacks she washed a lot of old, worthless dust rags most carefully and then bung them out to dry. Another time she went out on the street with her baby in her arms, and before all the passers by she took out her breast and began to nurse it in the utmost nonchalance.

After such attacks she generally goes to sleep for a while, and afterward has not the faintest recollection of what she has done or said. They have no relation to depression of spirits, but she is inclined to attribute the onset of her malady to worry from loss of a child.

Patient has a slight tremor about the mouth, especially just before speaking, and a spasmodic twitching of the left lower eyelid. Memory now rather bad.

Diagnosis. - Psychical epilepsy (petit mal).

CASE II.—A. F., aged six years, born in the United States of German parents.

Family History.—Phthisis in father's parents and sisters; father a potator.

Patient was born at full term, well developed; no instruments; three days' labor. She nursed and grew well until two years old, but was backward in talking and walking. Had a voracious appetite at first. Her present trouble began at the age of two years, when one day, while running about in her room, she suddenly fell over without any apparent cause. Then it was observed that she would at times run around in a small circle and end by falling on the floor. The attacks, occurring generally in the morning, finally became simply rotary to the left. Her eyes would begin to roll to the left, followed by her body turning to the same side; then she would begin to scream and talk unintelligently. If standing when the seizure came on, she would invariably fall on the floor. Sometimes she would suddenly start, run around in a circle four or five times to the left, sink to the floor, and in a minute come out of the attack. Her face would always get red and flushed at first, then pale. She has several such attacks daily for a week or two, then she may go for one to eight months without any.

She is well developed now, teeth very bad, very willful and disobedient, and does not learn readily. Suffers from enuresis nocturns at times. In the intervals between the seizures there is no spasm or rigidity of any muscles.

Diagnosis .- Rotatory epilepsy.

Case III.—D. S., eleven years old, born in the United States.

For a year or more has had attacks of mental excitement, during which he has an uncontrollable impulse to go out of the house. During one of these he wandered out and seems to have got into a state of mental aberration, and was found two days later in Brooklyn; he remembers only that two men picked him up. On returning home, in New York, he did not recognize anybody for a whole week. He would soon recover from such seizures and then go into a similar one again, or would sing, cry, or dance. Under treatment with tonics and bromides there has been marked improvement, and the attacks have gradually grown less frequent. He now complains of fronto-occipital headaches and at times attacks of vertigo and somnolence.

Diagnosis.-Automatism, epilepsy.

Case IV.—A. R., twenty-six months old, born in the United States

Four days previous to first spasm had a light fall out of bed, causing a slight bruise over the right eye which seems to have had no ill effect. Was able to talk quite well, but after the second attack did not utter a word for three weeks excepting some mutterings and mumbling which were unintelligible to the mother. During this period the motility of all parts of the body was unimpaired, but the child would frequently stumble and run its head against the wall and other objects, as if it were out of its mind. The surface of the body feels continually cold. While recovering from a seizure would scream and yell for a fortnight, and bite itself.

Now talks rationally, but at times as if it were foolish or delirious. Before last attack was a bright child, but is now forgetful. Is not vicious or peevish outside of such attacks. In appearance is very bright, burly, and intelligent.

Diagnosis.-Epilepsy (automatism).

Even these few histories go to show how diverse and manifold the psychical equivalents of epilepsy may be, and were we to go further into the enumeration of such cases we would find successively a vast variety of phenomena and transitional forms, from the mildest—such as epileptic vertigo, "absence" spells, etc.—to the severest, in which the strangest and most complex actions are performed, and emotion, violence, and rage are displayed.

I need scarcely refer to the fact that it is of the greatest practical and forensic importance for the practitioner to be able to make a correct diagnosis of psychical epilepsy. But this is in some cases extremely difficult, especially when the symptoms are of a mild type or when the seizures closely resemble those of hysteria, insanity, and so-called dual or triple personality. Not a few experienced diagnosticians have been shipwrecked on these cliffs. The name of epilepsia larvata, employed by the older physicians, is quite an appropriate title in a great many cases. Frequently it is only by observing such seizures when alternating with typical epileptic attacks, or occurring independently of them, but in paroxysms, in connection with other epileptic phenomena and stigmata, that the true nature of the disturbance can be detected.

In regard to treatment little remains to be said.

In dispensary practice it is difficult for both the physician and patient to follow out the therapeutic measures essential to success. However, the results of our clinic compare favorably with those obtained in others. On reading over our records, I can conscientiously state that no time or trouble has been spared, or none of the numerous methods and drugs recommended by the profession left untried in endeavoring to relieve this unfortuate class of patients.

To judge from the results that are recorded, it would appear that our old standby, the bromide treatment, still ranks the first in our therapeutic armamentarium.

Fleehsig's opium treatment has been in use in our clinic for nearly a year past. As the results of this last method are being embodied in a paper, to be presented by my colleague, Dr. Joseph Collins, I will content myself in this place with merely referring to this new plan of treatment. I may be permitted to say in advance, however, that it gives promise of very favorable results in suitable cases, and of being a most important addition to our therapeutics.

#### A CASE OF

CYSTIC TUMOR OF THE FLOOR OF THE NOSE.

By JOHN DUNN, M. D.,

RICHMOND, VA.

Cystic tumors of the nasopharynx are comparatively frequent. I have several times seen small ones in the region of the pharyngeal tonsil; in two cases they were bilateral. Cysts are sometimes found in nasal polypi. With this exception, however, intranasal cystic tumors are, to quote the words of Bosworth, "among the rarest of occurrences." Neither in Bosworth's Diseases of the Nose and Throat nor in Burnett's System of Diseases of the Ear, Nose, and Throat is mention made of a cyst situated in the floor of the nose. The following case is therefore of interest:

Mrs. B., aged twenty-six years, first noticed three months ago that in the "corner of her nose" there was assail swelling. For the past three weeks it had grown rapidly, until on November 24, 1893, when she came for consultation, the following condition of affairs had resulted: Externally the region where the left ala nasi joins the cheek is seen to be unduly prominent; in a measure the sulcus here is obliterated. Examination of the interior of the left nose anteriorly shows an oblong, rounded, fluctuating swelling, extending from the nostril junction for about three quarters of an inch along the floor of the nose; it reaches from the sæptum internally to the external wall of the nose. The greatest depth of the tumor is about a quarter of an inch; this can, however, be increased by pressing against the

angle of the nostril externally. No trace of the tumor can be seen along the cul-de sac between the upper lip and the alveolar process. This shows that the tumor is practically all intranasal, If, however, the little finger be inserted into the nostril and downward pressure be made, the tumor can be indistinctly felt in the cul-de-sac. The growth of the tumor has been painless. There are no inflammatory signs about its surface. It is fluctuating. A hypodermic needle was forced through the cul-de-sac into the tumor, and a syringeful of a thick, transparent, yellowish fluid was obtained. The tumor was opened with a knife from the cul-de-sac. The contents were forced out and the cavity packed with cotton saturated with a 1 to-1,440 bichloride solution. This dressing was changed daily and each time a saturated solution of boric acid was used for the purposes of cleansing the sac. After a few days the sac was washed out with tincture of iodine, following which it gradually diminished in size until, by the last of December, a complete cure had re-

In regard to the treatment of these cystic tumors (ranula, etc.), I would say the best results obtained at my hands have been from excising a portion of the sac wall, filling the sac with tincture of iodine, which is immediately washed out, and then packing the sac with cotton, which is to be changed daily until obliteration of the sac has taken place. It seems likely that the case was one of retention cyst, similar to those that occur with comparative frequency in the oral mucous membrane, chiefly on the inside of the lip. I am inclined to think its origin was just within the nose, its nearest point to the upper part of the cul-de-sac of the upper lip being too far distant for it to be likely that this cyst resulted from closure of an excretory duct of the oral mucous membrane, although such a thing is possible. Careful probing failed to reveal any condition of the lining membrane of the sac that would suggest the possibility of this being a case of Zahncyste (Zuckerkandl). There was no communication that could be made out with the teeth or with the antrum of Highmore, nothing to lead one to believe that any bone changes had given origin to this cyst, which must therefore be classed as a retention cyst of the floor of the nose.

### BOWEL INVAGINATION.

By F. BYRON ROBINSON, B.S., M.D.,

CHICAGO,
PROFESSOR OF GYNÆCOLOGY IN THE CHICAGO POST-GRADUATE SCHOOL;
GYNÆCOLOGIST TO THE WOMAN'S HOSPITAL AND TO CHA. ITY HOSPITAL

The gynecologist should be familiar with the anatomy, pathology, and treatment of all abdominal viscera. But it is not always possible to become familiar with all forms of abdominal surgery without experimentation on animals. Experiments on the human abdominal viscera are bought at too high a price and, besides, are unjust. For any ordinary abdominal surgeon to acquire passable knowledge of intestinal invagination he will need to experiment on animals, and for this purpose the dog is the most useful. Invagination is the projection of one portion of bowel into the adjacent segment. It is nearly always toward the rectum.

The cause of invagination is irregular action in the gut wall. The disordered movements of the bowel seem to be

due to a lack of cerebro-spinal control over the sympathetic nerves, or some local irritation may induce it.

Invagination is chiefly a disease of childhood, when the sympathetic nerve is not under such a decisive control of the cerebro-spinal axis as it is in later life. In childhood the large vascular supply, the active peristalsis, and rapid growth with an extensive nerve supply to the digestive tract, render the bowel liable to disorders. Patients dying of cerebro-spinal diseases are apt to have the invagination of death, as found in the autopsy. I have found several invaginations in autopsies on dogs and human beings, but they were invaginations of the dying. Just before death the cerebro-spinal axis often loses control and the intestines become wildly disordered through lack of normal functions of the sympathetic. The invagination of the dying is noninflammatory, and only the result of violent disorder among the bowels before they become still forever. But in the living, where we find the inflammatory invagination, the irregular action of the gut wall is the same factor in its production.

The statistics of invagination are significant as regards diagnosis. Invagination constitutes more than one third of all intestinal abduction. Twenty-five per cent. of all invaginations occur before one year of age; fifty per cent. occur before ten years of age. We may look for it especially in growing childhood. It has no previous history, but has simply a sudden onset. There is little doubt that the violent crying spells of babies lasting for several hours are cases of invagination which spontaneously disinvaginate. When young children are attacked with invagination, about ninety per cent. prove fatal. Shock kills them sometimes in twelve hours. Dr. Jaggard, of Chicago, secured a specimen by post-mortem which killed the child in about thirty hours. It was of the ileo-cæcal variety. The location of invagination is also significant in diagnosis. Fifty per cent. occur at the ileo-cæcal valve, thirty per cent. in the small intestine, and twenty per cent. in the colon.

The diagnosis of bowel invagination rests on—1. Pain, which is sudden in its onset. It is intermittent, because it does not cause complete obstruction. The dogs experimented on proved this. The pain is very severe and depressing. 2. Vomiting is not conspicuous, but arises. The dogs would not eat or drink, and so vomited slightly.

3. Tenesmus is very manifest, but especially so if the seat of the invagination approaches the rectum. 4. Blood in the stool arises in about eighty per cent. of cases. The blood comes from rupture of capillaries at the apex and neck of the invagination. Stools are mostly liquid from hypersecretion due to irritation. 5. A tumor can seldom be distinctly found. I could not locate a tumor in about a score of dogs.

The pathological anatomy I studied chiefly in the dogs used for experimental invagination and in several human cases. If one opens the abdomen of a dog under chloroform, seizes the bowel in the left hand, and lays hold of the gut with a vaginal dressing forceps, he can gradually push one piece of bowel into the adjacent segment. One had better wait until the first peristaltic wave of contraction has passed over. The invagination once started, glides

freely forward. But it will be necessary to suture it in the invaginated position or it will soon disinvaginate itself. In making the invagination, one produces a structure composed of three layers of gut. The outer layer is the intussuscipiens. The inner and middle layers are the intussusceptum. We then have the outer, inner, and middle layers of gut wall, with serosa against serosa and mucosa against mucosa. Where the outer layer bends and becomes the inner layer is situated the neck. The lower end of the intussusceptum, or where the entering layer bends to become the returning layer, is called the apex. The dangerous points in an invagination are at the apex, neck, and center of the middle layer. In the dogs I found the apex sloughing in four days. The neck did not give way so soon, for the reason that it is not still except by a fixed invagination. If the invagination increase or decrease, the neck will move, and thus it is not so liable to slough. The main change quickly occurred in the middle layer. The return venous blood was obstructed, and it rapidly became edematous and swollen. In the small intestine of a dog of thirty pounds it would swell as large as a hen's egg in two days, and frequently become gangrenous. The outer and inner layer suffered less. The gut above the invagination soon dilated and hypertrophied. The gut below the invagination continued very pale and anæmic. As the invagination became chronic, the changes in all the parts of the invagination became more pronounced. The middle layer, as well as the gut above the invagination, rapidly hypertrophies. The apex gradually sloughs away. The invagination becomes irreducible from ædema of the middle layer, but one can gradually squeeze the ædema out with the two hands pressing it; then by the aid of the finger below slowly push up the invagination. If the invagination becomes chronic, adhesions prevent the reduction.

The changes in an invagination in three days to a week were very extensive. The invagination vigorously disinvaginated, and would even tear out sutures to do it. I treated the invagination by anastomosis by the aid of my segmented rubber plate. The invagination is liable to produce bowel obstruction by (a) the mesentery narrowing the slit at the apex, (b) by thickening of the middle layer, (c) by some mechanical accident some indigestible substance might fall into the narrow slit of the apex. The rôle played by the mesentery is best observed by studying both a recent and chronic invagination. In an invagination of six inches long one can see that the mesentery is drawn out in the shape of a cone between the outer and middle layers. The longer the invagination, the tighter will be the compression of the roll of mesentery at the neck.

The middle layer may slough out entirely by becoming gangrenous at the neck and apex. It may be expelled per rectum; the gut may have its mucous membrane inside or outside. If the neck adheres to the apex sufficient to prevent fæcal extravasation, recovery may occur; but even then statistics show that nearly half of such persons die of stricture. Invagination is generally very acute in its action; but I know of one case in the ascending colon which lasted a year, and one case in a young lawyer which killed him in invaginated bowel-i. e., make the anastomosis some eight

two years. In the last case the invagination was in the transverse colon. It is surprising how small, pale, and thin the middle layer can become by the pressure of the outer and middle layers of the invagination.

Meteorism is not at all conspicuous in invagination, because invagination produces only incomplete obstruction, The pain arises from excessive peristalsis at the seat of invagination. Sometimes the invagination can not be disinvaginated, because the middle layer is so ædematous and enormously swollen that it would tear the gut to accomplish it. Of course, one can take the invaginated bowel between the two hands and squeeze it until much swelling disappears, and then, by the aid of the index finger below, one is enabled to disinvaginate very severe cases. If it be in a very young dog, the gut soon gives way, and the same will occur in a young child, as tissues are succulent and friable and soon become ædematous by blood stasis and infection. Also in older cases the adhesions play a rôle to prevent spontaneous or manual disinvagination. Again, the irreducible invagination is extensive and it would be certain death to resect all of it, so the only hope lies in artificial anus or anastomosis. It must not be forgotten that frequently after manual disinvagination it will require an artificial anus, or resection, or anastomosis. For, after the gut is disinvaginated, it is found that the apex has sloughed an annular zone or the neck has one or more perforations, any one of which will demand artificial anus, resection, or anastomosis. One may turn into the bowel lumen small patches of gangrene and fix them by a few Lembert sutures. Time is an all-important matter in such work, for the patient has already suffered a severe shock from the trauma of the invagination. The shock is a profound change in the abdominal vascular system and is manifested through the abdominal brain or sympathetic system. In irreducible invagination it will be frequently found that the only feasible method is anastomosis rapidly performed. Mine were all done with rubber plates.

The effect of anastomosing the bowel above to that below the invagination by the aid of the rubber plates, without resection or reduction of the invaginated bowel, is very marked. The animal becomes more quiet. Vomiting diminishes. If one kills the dog a week after the anastomosis or the irreducible invagination he will be surprised at the shrinkage of the invaginated bowel excluded from the fæcal current. It has shrunk a quarter, a third, or a half. It has atrophied and become quite pale. The dark venous congestion has mainly disappeared, and frequently the length of the invagination has diminished. The changed direction of the fæcal current was the cause of the shrinking of the irreducible invagination. Food traveling over the digestive mucous membrane is what entices blood to the gut wall through some nervous mechanism. But when the fæces travel by another channel they induce the blood to follow. So, really, the invaginated bowel excluded from the active digestive tract simply starves or shrinks. Fæces do not collect in the excluded

Experience has taught me to give a wide berth to the

inches above and eight inches below the seat of invagination so as to avoid pathological bowel walls and circulation as well as deranged peripheral nerves. In small children and small puppies the gut is so small and friable that it is almost impossible to perform anastomosis. If an artificial anus is made and long maintained in a young patient, the gut below will grow but very little on account of changing the fæcal current, and in this way the future hope of re-establishing the intact digestive tract is lessened. It may be remembered that the old invagination might disinvaginate after weeks or months and the slough at the apex allow fæces to trickle into the abdominal cavity. Grafts torn from the omentum should be used on the anastomosis.

## ASEPSIS,

WITH ESPECIAL REFERENCE TO ABDOMINAL SURGERY.\*

By LOUIS FRANK, M. D.,

INSTRUCTOR IN BACTERIOLOGY
AND ASSISTANT TO THE CHAIR OF ABDOMINAL SURGERY AND GYNÆCOLOGY,
KENTUCKY SCHOOL OF MEDICINE'
VISITING PHYSICIAN TO LOUISVILLE CITY HOSPITAL, ETC.

The cause of sepsis in surgical wounds is always the entrance of pyogenic organisms, without which there can be no suppuration infectious in character. This may occur from extrinsic sources or may be due to noxious matter from within, such as cyst contents, Falloppian-tube contents, etc. Our object, then, is to prevent contamination. How is this obtained? Infection from extrinsic causes may be avoided only by the strictest observance of certain rules in the preparation of the patient, operator, his assistants, the instruments, and dressings. It is only those things which come in direct contact with the wound that cause pus. Atmospheric infection is practically nil, for we know that very few, if any, pyogenic microbes are found in air. Of course, no one would operate in a ward or room containing any person with an infectious or contagious disease or in a dust-laden atmosphere. It has been shown by repeated examinations of air that ordinarily and usually no pathogenic germs are found; still we must, if possible, exclude even this remote factor. This necessitates specially prepared operating rooms, which should be constructed so as not to present any corners, the walls being painted with a washable paint and the floor made best of an artificial cement, with a drain so as to permit of its being flooded. All the tables in the room, whether for the patient, dressings, or anything else, should have either a plate glass or smooth marble top, so as to permit of being most easily cleansed. The woodwork, if any, should be of the highest finish for the same reason. Such an operating room, with all conveniences for modern surgery, has just been completed at the St. Joseph Infirmary, this city. Leather-top tables are an abomination and should never find a place in the operating room.

Before the operation the walls and furniture should be wiped with a moist, clean towel, but never dusted. This may be easily done and the walls remain perfectly white if they are painted with a zinc paint and then varnished.

But these preparations are of less importance than the

\* Read before the Falls City Medical Society, November 2, 1893.

preparation of the operator and his assistants, for they are one of the most frequent sources of wound infection. The operator and assistants should each have taken a hot bath and changed his linen either the night before or the day of the operation, and thoroughly washed the hair and beard. In fact, long hair or beard is out of place on an operator, and often have I seen perspiration run over the face and through the beard or trickle down from the scalp and fall in the wound. Do you wonder that sepsis is sometimes unexplained? Immediately before the operation, having taken off coat, vest, collar and cravat, and cuffs, the hands and arms should be thoroughly scrubbed, the assistants being just as careful in this respect as the operator himself, for even if they do not handle the wound, they do come in contact indirectly with it, in that they handle instruments, sponges, etc. In fact, all spectators should be compelled to follow the same rules, as an emergency may arise or they may forgetfully or unconsciously touch the instruments, etc. They should also don long white aprons with sleeves, as should also those to be engaged in the operation. These aprons should cover the clothes entirely and should have been previously thoroughly sterilized by moist heat. To return, however, to the cleansing of the hands, which, gentlemen, is a most important factor in this chain we are forging, and one that is often not carried out as it should be. The length of time spent in scrubbing is not so important, as it depends upon practice, dexterity, and knowledge of where and how to clean. How often have we seen men spend ten to fifteen minutes scrubbing the hands, but with what a brush! With perfect safety a brush may be used only once. It should be new (and they can be purchased for fifty cents a dozen) and have been previous to use sterilized for a half-hour in streaming steam. After being used once it should be thrown away. In this city there is only one operating room where I have seen this method followed; in some other places the same brushes are used time and time again, the only precautions being to keep them immersed in the interval in a 1-to-2,000 solution of bichloride of mercury. This solution of bichloride merely retards the growth of the organisms for the time being; it does not destroy the spores, so that when we again use our brush we are doing what we try not to do-instead of cleansing, we are bringing our hands in contact with organisms. Even after washing out our brushes thoroughly and resterilizing in steam, they may only be used three or four times at the most, so that the plan of buying cheap brushes and using them only once is really less expensive and far

Having then thoroughly cleansed the hands and thus mechanically removed all the organisms possible, they may be immersed in a 1-to-1,000 bichloride solution for three to five minutes and rinsed in clean sterilized water or washed in alcohol. The mechanical cleansing is, however, of the most value. The nails must, of course, be pared and cleansed. Simply immersing the hands for a few minutes in a strong solution of an antiseptic is of little if any value, but is only practiced by those who pretend to know and are really ignorant of asepsis.

The operator, then, having prepared himself, should pre-

pare his patient quite as carefully. The patient should have, previous to the operation, a bath and the parts should be shaved, and, in abdominal work, this shaving should extend to the pudendum. After shaving, the parts should be thoroughly washed again and covered for at least twelve hours with a towel saturated in a solution of bichloride (1 to 2,000 or 1 to 3,000). At the time of the operation, this towel being removed, the parts should be thoroughly washed with ether or with alcohol to remove the fat, thus getting away any dirt or septic matter that might be in the deeper layers of the skin.

In such operations as vaginal hysterectomy for cancer the cavity of the uterus should have been previously curetted and the vagina cleansed with bichloride solution. The patient should be attired on coming into the operating room in nothing but a gown (which should be thoroughly clean) and a pair of new stockings. After being put upon the operating table, it is only necessary to cover the chest and legs with a clean blanket, or, in doing operations upon other portions of the body, to cover all parts of the body except that which is to be exposed to operation. These blankets may in turn be covered with sterilized towels. In abdominal work it is especially desirable that thorough purgation should have been done, which is best accomplished by means of salts given every morning for several mornings previous to the day of the operation. This cleanses out the bowels thoroughly so that there will be no distention, and also prevents extravasation of the intestinal contents, should we be so unfortunate as to damage the bowel. So much, then, for the patient.

The instruments in abdominal work, or in work where the operator has time to prepare for the operation, should be sterilized, best in a steam sterilizer; by instruments I mean also needles and sutures. If this is not possible, and the sterilization of instruments must be rapidly done, it can best be accomplished by immersing them for ten or fifteen minutes in boiling water, to which it is well to add a little soda to prevent rusting of the instruments. The instruments coming out of either the soda solution or the sterilizer should be kept covered with water which has been boiled and which is still warm. The instruments should be rinsed repeatedly in water during the operation to wash off any blood clots which may have formed on them. The sutures, if we are to use silk or worm gut, which are far preferable to catgut, may be sterilized also, as I have said, in the incubator, or by means of boiling water. Of course, this method is not applicable to the sterilization of catgut. In the use of catgut it is probably best to follow the method used in von Bergmann's clinic as given by Schimmelbusch. This consists of "immersing the catgut sutures in a one per-cent. solution of sublimate in eightyper-cent. alcohol, in which they are left at least fortyeight hours, but even better still a longer time. This sublimated alcohol is better if changed every two days until the fluid remains perfectly clear; they are then preserved for use in ordinary alcohol." By this method it has been shown that catgut is rendered perfectly aseptic. I have examined bacteriologically silkworm gut and catgut which had been sterilized in these ways, and have never been able to demonstrate any organisms. The preservation of catgut in various oils is, in my opinion, not a good method, as in examinations of catgut preserved in a three-per-cent. carbolized oil, and also tendons which had been preserved in the same way, I have been able to demonstrate numerous colonies of micro-organisms. Whether or not these were pathogenic I have not had an opportunity of demonstrating by experiments, but have seen stitch abscesses follow their use.

As to sponges and material that is to be used for sponging during the operation, I believe the cheaper and better plan is to use especially prepared and aseptic sponges. The method of preparing these sponges which seems to me to have given the best results is that of rendering them aseptic by means of sulphurous acid and repeated washings in sterilized water, then immersing in absolute alcohol. This absolute alcohol sometimes hardens the sponges, but they again become soft after being soaked in water. The method of keeping sponges sterile by immersing in bichloride solution and in carbolized solution is a bad one, as in the case of sublimate it is with great difficulty that we are able to wash the sublimate from the pores of the sponge, and may in this way carry the sublimate solution into our fresh wound, which is undesirable, as you all know. In the case of carbolic-acid solution, I have found that my sponges soon rot. This, however, is not due to the formation of any bacteria, but seems to be due to the action of the water. Sterilized gauze may be used also, but can not be rinsed as nicely as sponges or used more than once, and so is really more expensive.

Where it is desirable to hold back the intestines in abdominal work, I think the large flat gauze sponges are more serviceable than the others. We should, however, always take the precaution of tying a string to one corner so as to be able to bring them easily out of the cavity again. If these are not at hand, a sterilized towel may be used equally well. No water to which any chemical germicide has been added should be brought in contact with a fresh wound, nor in the abdominal cavity to any wound even where pus has been present, as results have shown that these strong germicides destroy the epithelium covering the peritonæum, thus rendering absorption much easier. At the same time they do not destroy the organisms; the best that they can do is to retard their growth for a short while. So that in irrigation of the abdominal cavity or in sponging the abdominal cavity or fresh wounds that the surgeon may have made anywhere, it is advisable to use sterilized water. It is not necessary that this water should be filtered, nor is it necessary that it should be distilled water; it can be sterilized by simply boiling and allowing it to cool, when the sediment of mud which we find in our water here will settle to the bottom, giving us clear water above, which may be used. In wounds, even where extensive contamination of the peritonæum has taken place by rupture of pus tubes, the organisms may be almost completely removed mechanically by irrigation with this sterilized water. Of course, we also rely upon drainage to carry off septic matter remaining behind and in shutting off the cavity from above to prevent contamination. For this drainage it is preferable to use sterilized gauze, should the adhesions have been extensive, or should there be a large cavity which should heal from the bottom, or should there be much bleeding. Drainagetubes may also be used with the gauze. In the use of gauze a point which I believe is important, especially in procuring good drainage, is to be careful not to pack the gauze too tight. Be also careful not to compress the intestine. If we pack too tightly, we really prevent, to a certain extent, what we desire to obtain-perfect drainage. Also, in the use of gauze, an objection which we have to it is the fact that frequently sinuses are left behind. These are not so often seen in the use of the drainage-tube; in fact, very seldom if provisional sutures are put in which are closed when the drainage-tube is removed. The ideal drainage tube is the glass one, not only for the reason that it does not bend or is ever compressed, but can also be most easily sterilized. It should be sterilized at the same time we sterilize our instruments.

In suturing we may use the same needles repeatedly, but they should not pass through the hands of too many assistants. The needles and sutures should be kept covered during the operation, and should be only uncovered just previous to use, they, of course, having been sterilized, as I have mentioned before, along with the instruments. Even, however, with all this care it has been shown that infection may take place in the stitch wounds, due to organisms in the deeper layers of the skin which can not be removed (Welch).

Another point in suturing to which not enough attention has been paid is tension on the suture. We should not make great tension for the reason that if we do we cause the mechanical death or necrosis of tissue non-septic in character, but which readily becomes septic, or at least affords a nidus for organisms. In dressing, after the wound is closed, it should always be thoroughly dusted with crystallized iodoform. Iodoform is not only an antiseptic on account of the iodine it contains, but also prevents germ growth by its rapid absorption of the secretions and its rapid drying, thus sealing hermetically any wound to which it may be applied, provided, of course, this wound is not too great in area or the discharge of serum therefrom too great in quantity. After dusting thoroughly with iodoform we may put on sterilized gauze. The use of gauze impregnated with bichloride of mercury is bad practice, as is also the use of gauze which has been impregnated previous to the operation with iodoform. In the case of bichloride we have the crystals of the bichloride in the meshes of the cloth, which are perfectly inactive as preventers of germ growth, as the only way possible in which mercury can act is in solution. Now, if the mercury is in solution where gauze is necessary, then we do not obtain perfect absorption of our wound secretion. The same can be said of iodoform gauze. The only way in which iodoform can be used in connection with gauze is to dust it into the gauze and rub it in at the time of the operation. In impregnations with iodoform it is always necessary to use glycerin and some solvent of the iodoform. These, of course, keep the gauze necessarily moist, and we have the

same thing as we do in the use of moist bichloride gauze. Having thoroughly covered the wound with gauze, we bring over this a layer of sterilized cotton, and then either a flannel binder which has been thoroughly sterilized by steam or the Scultetus bandage. Where we have used a drainage-tube or where it is necessary to leave on forceps for the control of hæmorrhage, we can pack around these forceps with gauze, or with the drainage-tube we may leave an opening for the tube to pass through the dressing, covering the opening of the tube with sterilized gauze and with a rubber dam. This rubber dam and also the pin with which it is held should have been sterilized the same as our instruments in the steam sterilizer.

The point which I have desired to bring out in this paper is the entire absence of any mechanical germicide during the operation, except in case of preparing the hands, and even then it is not necessary and often gives a false sense of security. Bichloride is perfectly inactive as a germ destroyer in the solutions ordinarily used. Its only action is to prevent the growth of organisms for a short while, and at the same time it renders the tissues with which it is brought in contact better able to take up and absorb these organisms. Mechanical removal of offensive matter is the ideal method. What we desire is absolute cleanliness. We can very often procure an aseptic condition in a septic wound by these methods. In cases where we have removed pus tubes and where we think we have left behind a portion of the tube, or, as in cases of possible ligations in appendices, where we desire to render the canal aseptic, this may be best done by touching with pure carbolic acid and stitching the serous coat over the end.

After abdominal operations the pulse should be carefully watched, as it is really a better indicator of the condition inside of the abdomen than the temperature. By it we are enabled to tell a great deal more. I have seen abdominal cases where the temperature would go up to 104° F. where the wound had been reopened and absolutely no pus found. The cause of this rise in temperature may sometimes be found in the excessive use of iodoform, but this should not argue against its continued use. We might as well argue against the use of morphine because some patients have peculiar idiosyncrasies for this drug. We should purge early enough and thus drain through the bowel as well as through the external wound. Salines are the ideal purgatives, but they may also be contraindicated where there is much vomiting or nausea. In these cases it is better to use calomel, repeated every half-hour, with high enemata of glycerin and water, or of water containing in solution salts for the purpose of producing catharsis. After the bowels once begin to move, when our patient begins to pass abundant gas, we may usually feel easy.

In closing, I desire to express my thanks to my friend Dr. Wathen for suggestions made and observed while I was assisting him in his work.

The Section in Neurology of the New York Academy of Medicine.—At the meeting of the 16th inst. Dr. Frederick Peterson was elected chairman and Dr. Joseph Collins secretary for the ensuing year.

THE

# NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 24, 1894.

## TRANSFUSION AND SENSATIONAL JOURNALISM.

The effort to save the life of another at the risk of one's own life has always been held one of the highest forms of heroism, for greater self-sacrifice and nobility can hardly be imagined. It is but natural, then, that occurrences of this nature should ever attract our interest and admiration. Accordingly, to our daily papers such cases are always welcome material.

To the lay mind, medical and especially surgical matters have always been associated with mysticism (the direct cause of unwholesome curiosity) which time has not yet succeeded in entirely removing. When, then, we find the effort to save life at the cost of personal danger associated with surgery we have all the material for ministering to a morbid appetite and an unhealthy curiosity in the lay reader. To the catering to this demand our daily press is ever tempted, and, in so far as it yields, and especially where it exaggerates, its action can not but be considered sensational and heartily to be deprecated.

The operation of transfusion is especially the occasion of this sensationalism, and during the present winter several instances have occurred in which, in bold and startling headings and ridiculous, theatrical, and generally erroneous details, our daily press has recorded this operation.

To bleed a patient is surely not such a terrible thing; in fact, it was formerly done most extensively and as a therapeutic procedure often of great value, and it is certainly true that many men to-day would be healthier and stronger for the losing of a little blood. It is not to be supposed that in transfusion an intelligent operator would select a weak and anæmic donor; both for the sake of the recipient and for that of the donor, such action would be absurd. And a competent operator is not likely to remove from the donor a quantity of blood larger than he is well able to lose. To the full-blooded donor the disposal of a small quantity of his blood will scarcely cause anxiety, and, selfishly speaking, it must be a matter of profound indifference to him whether it enters the vessels of another or is thrown away. Where, then, lies the "heroism" of the properly selected and properly bled donor? Surely it is only in the columns of the paper which sensationally reports it. That it is a humane thing to give one's blood to another who needs it can not be denied; but that it is heroic, when one does not need the lost blood and may even be benefited by its withdrawal, is absolutely false.

As a matter of fact, the donor of the blood is seldom, if ever, injured by the operation, and we can not recall a case in which, when the operation was properly done, he ever suffered more than the merest temporary inconvenience therefrom.

The cure for such unhealthy journalism rests with the papers themselves. If they must publish such things, let the reports be written by medical men and let them be honest. But, better yet, let them not be published at all, for the absurdity of "popular" medicine and surgery as presented by our non-professional press is self-evident.

## MINOR PARAGRAPHS.

THE ÆTIOLOGY OF HEADACHE,

In a recent number of the Revue générale de clinique et de thérapeutique Dr. S. Vermel, after a thorough study of the subject, says that he is inclined to attribute all headaches to an oversensitive condition of the sympathetic nerves controlling the peripheral vessels of the cranium and brain, or to an angeioneurosis. It may be asked at once, he says, how the same symptoms, from the same cause, can be present in diametrically opposed conditions, such as plethora and anæmia, febrile and apyretic diseases, for example. The idea that the seat of pain is in the cortex has not been substantiated, for when a cortex is irritated there is locally only an hallucination of pain; the real pain is exhibited on some part of the body. Then, if the attack of cephalalgia is not due to local irritation of the cortex, the seat of the trouble must be in the meninges. It is to dilatation of the vessels of the meninges, causing intracranial pressure, that the pain is due. The vascular dilatation extends to the minute blood-vessels in the region of the pituitary body, rupture of which gives rise to the epistaxis from which patients so frequently suffer during an attack of headache. It is clear how this explanation answers for hyperæmic conditions, but how does it account for the same symptoms in anemia? In anæmia there is a qualitative and not a quantitative change in the blood, the amount of fluid in the vessels remaining the same. In veritable anæmia from excessive depletion of the system, as from hæmorrhage or cholera, the condition is different; but from the anæmia coincident with neurasthenia, hysteria, chlorosis, and so forth, there is, so far as quantity is concerned, the same condition as in hyperæmia.

In anemia the vessels are very prone to dilatation, producing an exaggeration of the intracranial pressure, in consequence of overexcitability of the vaso-motor centers allowing of local hyperemias.

The author definitely states that the seat of pain in headache is always in the dura mater and not in the cortex; that the pain is provoked by compression of the dura mater produced by increased intracranial pressure; and that this is true of all headaches, whether neuroses, or of toxic or mechanical origin—such as diseases of the brain or of the meninges, constipation, etc., or of reflex origin.

### AN OBNOXIOUS LAW.

In the trial of a suit to recover damages for injuries sustained on one of the elevated railroads of New York it came out recently that not long ago the State Legislature had enacted a law containing a section making it incumbent on the court in such cases to order a physical examination of the person alleged to have been injured. In accordance with this provision of the law, Judge Pryor appointed two physicians to examine the plaintiff, and a referee to be present at the examination, to see that justice was done. The plaintiff in this case is a young woman, and her counsel objected strenuously to such an order alleging that the law was unconstitutions, and that to carry out

such an order was to violate one of the fundamental rights of a citizen. We have no doubt that these objections are well founded, and indeed the judge himself seems to have thought as much, but there was nothing for him to do but to obey the law. It was said by the late General Grant that the best way to obtain the repeal of an odious law was to enforce it, and it is to be hoped that this attempt of Judge Pryor's to carry such a law into execution will bring the matter up in such a light before the Legislature as to secure the speedy repeal of the law. Not only is the enforced examination of anybody's person an outrage, but a physical examination at the time that a suit is brought is in most instances well-nigh useless as bearing upon the merits of the case. It is to be hoped that this case will not be allowed to drop out of the attention of the public. The reflections that any right-minded person could not avoid falling into in regard to it ought to lead to a general demand for the blotting out of so unjust a statute.

#### PARESIS OF THE SUPERIOR RECTUS.

This affection, which has long been considered rare, was the subject of a paper read at the Section in Ophthalmology and Otology of the Academy of Medicine last Monday night, by Dr. Alexander Duane. He has seen a number of cases, and believes that they are by no means uncommon. The symptoms are vertical diplopia, often present only when the eyes are turned upward, with tilting outward of the image formed in the eye with the affected muscle, and exophoria in varying degrees with the attendant symptoms. Both superior recti may be affected, or a compensating spasm of the inferior oblique may cause the appearance of paresis of both superior recti. Repeated examinations appear to show that the condition remains about the same, except that the exophoria slowly increases. Usually no cause has been found. It appears mostly in young persons, refractive errors are not necessarily present, and it probably dates from childhood, possibly from birth. It seems not to be of nerve origin, but to be a weakness of the muscle itself. Dr. Duane recommends for the treatment exercise of the internal recti by prisms, and rarely advancement of the paretic muscle. Prisms with the bases in are sometimes worn with advantage for distant vision, but when the eyes look downward they are not needed to the same degree; so different glasses should be used for reading.

#### VIVISECTION.

THE American Association for the Spread of Knowledge upon the Extent and Existing Methods of Vivisection asks the assistance of the medical profession in its efforts to prevent the infliction of unnecessary suffering on the animals used in the laboratories, in class demonstration, and by medical students. "Believing on good evidence which we shall be happy to submit to you," says a circular issued by the association, "that vivisection is often practiced in a needlessly cruel manner, convinced that many abuses exist which could be reformed without any loss to science, knowing that the young student passes through a period of insensibility to the sight of suffering, a condition from which the mature physician is fortunately exempt, we solicit your co-operation in our efforts to save animals from useless torture. We feel that our best suggestions and our most effective help must come from the medical profession itself, especially from those eminent physicians whose labors in the service of humanity give their words and example an authority which would do much toward abolishing the evils to which we venture to call your attention." This is most tem-

perate and reasonable, and we feel that the association ought to be accorded the hearty co-operation of physicians. The secretary's address is No. 58 West Fifty-seventh Street.

# LECTURES TO PHYSICIANS ON ELECTRICITY AND MAGNETISM

In view of the daily increasing importance of electrotherapy, the interest that attaches to electricity itself is constantly becoming more clearly evident to physicians, and the necessity for a more widespread and detailed acquaintance with the physics, the principles, and the measurements of electricity and magnetism is apparent to many physicians. It will interest our readers to know that a request has been made by several well-known physicians for a series of evening lectures on this subject from Mr. A. E. Kennelly, vice-president of the American Institute of Electrical Engineers and chief electrician of Mr. Edison's laboratory, Orange, N. J. It is proposed to hold this series of ten lectures at the Mott Memorial Hall on Tuesday evenings, beginning on March 6th. They will be illustrated by lantern and apparatus, and opportunity will be given for inquiries at the close of each lecture. Subscriptions will be open only to physicians and post-graduate students. Further particulars may be obtained from Mr. J. W. Gladstone, of No. 110 East Twenty-third Street, New York.

### THE MEDICAL PROFESSION IN HOLLAND.

THE curious story comes from Chicago that recently a Dutch physician of that city inserted a fraudulent advertisement in a Dutch medical journal, announcing that free transportation and an income of \$5,000 a year was guaranteed by the Government to a physician with the Dutch qualification, and requesting applicants for the place to forward their diplomas for inspection. The Chicago Dutchman is said to have alleged as his reason for inserting this advertisement that when he came to this country an article had appeared in one of the Dutch newspapers saying that only the least successful of the physicians of Holland found it necessary to leave their country. It is further stated that many answers have been received by the Dutchman, but we do not see how that fact either proves or disproves the statement made in the Dutch newspaper, for the quality rather than the number of the applicants would have to be known to settle that question. It is suspected that the man either wished to obtain a diploma which he could parade as his own or else designed selling these diplomas to unqualified persons in quest of an opportunity to practice.

### THE STATE COMMISSION IN LUNACY.

The present aspect of the controversy between the commissioners and the superintendents of the State hospitals for the insane is so petty as to take the dispute out of the limits of things that the medical profession cares to give its attention to. The commissioners are harping upon the allegation that the superintendents had lavished money in the purchase of wines, eigars, and delicacies, and the superintendents retort that the commissioners showed no hesitation in availing themselves of these comforts on the occasions of their visiting the various institutions. If the contestants will persist in giving prominence to this trivial feature of their controversy, they can not expect interest to be taken in it by those who only seek to have the State care of the insane as humane, efficient, and inexpensive as possible.

#### ITEMS, ETC.

The German Medical Congress .- The author of a printed circular dated Wiesbaden, January, 1894, but having no signature, states that he has received from Dr. Emil Pfeiffer, acting secretary of the Congress für innere Medicin, a statement to the effect that, in order not to conflict with the coming International Medical Congress, the next meeting of the German or ganization will not be held until the year 1895, when it will take place in Munich.

The Nurses' Bureau of the Academy of Medicine was opened on February 5th, for the purpose of providing reliable nurses for physicians and for patients. Each nurse who registers will be charged a fee of \$2 a year for registry, and will be required to have an indorsement by two reputable physicians, who will be written to minutely as to their knowledge about her character and capacity as a nurse. Each time that a nurse is taken out by a patient a fee of \$2 will be required of the patient for this privilege. When a nurse leaves a case the physician for whom she has been nursing will be written to for minute details as to her management of it, and in many instances the friends of the patient will be written to also. If a nurse notably fails in the performance of her duties she will not be permitted to have the privileges of the bureau.

Army Intelligence .- Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 11 to February 17, 1894:

A board of medical officers, to consist of Alden, Charles H., Colonel and Assistant Surgeon General; FORWOOD, WILLIAM H., Lieutenant Colonel and Deputy Surgeon General; SMART, CHARLES, Major and Surgeon; REED, WALTER, Major and Surgeon; and MERRILL, JAMES C., Captain and Assistant Surgeon, is constituted to meet at the Army Medical Museum Building in this city (Washington) on the 12th day of March, 1894, at ten o'clock A. M., for the examination of candidates for admission to the Medical Corps of the Army.

SMITH, JOSEPH R., Colonel and Assistant Surgeon General, is granted leave of absence for one month and ten days, to take effect upon the adjournment of the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894.

Naval Intelligence, Official List of Changes in the Medical Corps of the United States Navy for the week ending February 17, 1894.

PRICE, A. F., Surgeon. Ordered to the Torpedo Station, Newport, R. I.

AMES, H. E., Surgeon. Detached from the Torpedo Station and ordered to the Richmond.

BARNUM, M. W., Assistant Surgeon. Ordered to temporary duty on the Ranger, and, upon the reporting of relief, detached from the Ranger, ordered home, and to wait orders. SMITH, G. T., Passed Assistant Surgeon. Detached from the

Naval Hospital, Chelsea, and ordered to the Ranger. PIGOTT, M. R., Assistant Surgeon. Detached from the Richmond and ordered to the Naval Hospital, Chelsea.

BAYLEY, T. B., Passed Assistant Surgeon. Detached from the Machias and ordered to the Richmond.

KEENEY, JAMES F., Passed Assistant Surgeon. Died on board the U.S. Steamer Ranger, February 10, 1894.

## Society Meetings for the Coming Week:

MONDAY, February 26th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association. TUESDAY, February 27th: New York Academy of Medicine (Section in General Surgery); New York Dermatological Society; Buffalo Obstetrical Society; Boston Society of Medical Sciences (private).

WEDNESDAY, February 28th: New York Academy of Medicine (Section in Laryngology and Rhinology); American Microscopical Society of the City of New York; New York Pathological Society; New York Surgical Society; Metropolitan Medical Society (private), New York; Auburn, N. Y., City Medical Association; Medical Society of the County of Albany, N. Y.; Berkshire, Mass., District Medical Society (Pittsfield); Philadelphia County Medical Society.

THURSDAY, March 1st: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, March 2d: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, March 3d: Clinical Society of the New York Postgraduate Medical School and Hospital; Manhattan Medical and Surgical Society (private), N. Y.; Miller's River, Mass., Medical Society.

## Retters to the Editor.

#### A MATTER OF NAMES.

NEW YORK, February 6, 1894.

To the Editor of the New York Medical Journal:

Sir: In the Journal of January 27th there appeared the report of a clinical lecture delivered in October by Dr. Robert T. Morris, entitled An Inch-and-a-half Incision and a Week-and-ahalf Confinement in Appendicitis. While the title of the paper and its general tenor might perhaps be fairly considered open to criticism, yet it is not my purpose now to find fault with them.

The part of the lecture to which I wish to take exception is that in which the traditional A. and B. of medical literature give way to Jones and Smith. There are in the latest medical directory six Joneses and twenty-two Smiths, and as one of the former I object to an innovation which is in exceedingly bad taste outside of Punch and Puck. It is quite possible that difference of opinion with reference to the advisability of an operation in appendicitis may occur between medical men, but, if it ever did or should manifest itself in terms such as the author quotes, then the pencil of Hogarth would not libel the profession of to-day any more than it did that of his time.

By all means let Brown, Jones, and Robinson still adorn a tale in general literature, but let the literature of our profession stick to plain A. and B. or X., Y., and Z, and let medical writers go about their work in sober earnest.

# Proceedings of Societies

SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

Meeting of January 3, 1894.

The President, Dr. FREDERICK H. WIGGIN, in the Chair.

Carcinoma of the Breast,-Dr. F. H. Wiggin presented a patient showing the result of operation for this condition. She

was sixty-one years of age and had a good family history. In June, 1892, she had first noticed a tumor in the left breast which had been of the size of a robin's egg. During the ensuing year it had grown rapidly and had become painful. By the advice of a quack it had been poulticed until the skin had become ulcerated. When seen by the speaker on December 12, 1893, there had been a large tumor in the center of which was an extensive ulceration discharging very offensive pus. The axillary glands were involved. The diagnosis of carcinoma had been confirmed by microscopical examination by Dr. Dunham, and the operation had been performed on December 13th. The tumor had been so large that after its removal there had been a space measuring about five inches in its short diameter. Recalling Dr. Shrady's method of sliding the skin to cover in such areas, an incision had been made at right angles to the short axis of the oval, and a flap above and below had been slid in to fill up this oval area. This had left a large oval above, but, by dissecting up a long flap across the front of the thorax, the integument had been sufficiently loosened to admit of closing this gap. There had been considerable oozing after this extensive dissection, but the free application of peroxide of hydrogen had almost immediately stopped the hæmorrhage; and when the dressing was changed five days later, it had been hardly discolored. Primary union had occurred except at one small point, where, owing to excessive tension, the part had sloughed. The result had been certainly better than that usually following skin

Diphtheritic Paralysis of the Neck Muscles.-Dr. W. R. Townsend presented a little girl who had been brought to the clinic at the Hospital for Ruptured and Crippled with a diagnosis of Pott's disease. It had been found that the child had had diphtheria last November, and had recovered from it, but that one or two weeks afterward she had fallen from her chair, and then the head had been noticed to drop forward. In the past year or two a number of such cases had been seen at the hospital where the diphtheritic poison had affected the posterior muscles of the neck, allowing of a dropping forward of the head and an undue prominence of the cervical vertebræ. If this were a case of Pott's disease, it would be impossible to put the head into normal position by simply lifting it with the hand, and, moreover, there would be thickening of the vertebræ. Another important distinguishing feature was that in the morning on awakening, the child was able to hold up the head better than later in the day.

Again, in Pott's disease there was much pain if the head were moved, and marked spasm of the spinal muscles. In this case both these symptoms were absent. The position of the head was also slightly different from that usually found in Pott's disease; the chin pointed toward the chest and was exactly in the median line, while the majority of cases of cervical bone disease deviated to one or the other side. The sudden onset and the previous history of diphtheria were also aids to the diagnosis.

Anomaly of the Rectum.—Dr. J. M. Byron presented a female child whom he had first seen two days after its birth. He had not seen an exactly similar case in this city. The rectum opened into the vagina, and the faces were retained perfectly by a sphincter in the vagina until the rectum became filled with facal matter. No operation had been advised when the case was first seen because there seemed to be a difference of opinion among surgeons as to the desirability of operating at an early age.

Dr. J. F. Erdman said that the proportion of recoveries after operation for fistula connecting with the vaginn was exceptionally large. He would be in favor of deferring operation until the child was older.

Crushing Injury of the Foot.—Dr. Wiggin exhibited a patient who had sustained a compound, committed fracture of the tarsus. The tendons had been sutured and deep buried sutures had been passed through the structures of the foot.

Thiersch's Skin Grafting .- Dr. J. F. Erdman presented a case illustrating the value of this method of grafting in certain extensive injuries of the soft parts. The patient was a man, forty-four years of age, a brass worker, who while shoveling slag into a crusher had had his arm caught in the machine, and an area of about fifty square inches around the elbow entirely denuded so that the tendons and muscles in this region had been exposed as though by a careful dissection. There had been a complete laceration of the brachial artery just above the elbow and of the radial and ulnar about an inch below the elbow; the external and internal cutaneous nerves and a portion of the median had also been injured. When first seen about ten days after the injury, there had been a slough on the anterior surface of the forearm of about forty square inches; there had been considerable ædema of the hand, which had been cold and blue, and there had been no pulsation over the radial and ulnar arteries. About twenty-seven inches of skin graft had been applied according to Thiersch's method. The grafts had been placed directly on the supinator, pronator, and portions of the biceps muscles, and also on the brachialis anticus and triceps. There had been no recovery of sensation of external and internal cutaneous nerves, but there had been some in the parts supplied by the median nerve. There had been no return of circulation in the main vessels of the extremity. It was worthy of note that there was no cicatricial contraction of the parts, and that the patient was able to go to work about fifteen days after the grafting.

Since having this case he had tried the skin grafting according to Krause's method, and in another case of the kind he would prefer it, as the grafts were more flexible. In the Krause method simply the true skin was cut off, and the flap transplanted as in Thiersch's grafting, being careful to take off all the areolar tissue and to apply it to a dry surface. In the Hirschberg method the graft included the areolar tissue, and was stitched to the cdges of the part to be grafted.

Dissections of the Ear.—Dr. Gorham Bacon exhibited a number of beautiful dissections of the ear made by Politzer.

The bone preparations showed the relative positions of the tympanic cavity and mastoid cells.

The Effect upon the Lungs of Effusion into the Pleural Cavity.—Dr. EGBERT LE FEVRE read a paper on this subject and illustrated the physics of the subject by an interesting demonstration. (See page 235.)

Dr. HERMANN M. Biggs discussed the ætiology. He said that in considering the ætiology of pleurisy with effusion the active factors might be included under three heads-viz., microbes, chemical substances in the blood, and new growths. The microbic type might be subdivided into infectious new growths. such as tubercle, actinomycosis, and possibly gummata, and those in which the process was purely inflammatory. The bacteriology of simple plearisy with effusion had been pretty thoroughly investigated during the last few years, and a number of micro-organisms found. In the large majority of cases these were confined to a few types. In about seventy-five per cent. of all sero-purulent or purulent pleurisies which were not tubercular one of three types had been found-the pneumococcus of Fraenkel, the staphylococcus, or the streptococcus. The pneumococcus of Fraenkel was present in a very much larger proportion of cases than any other form, and in the type of pleurisy

in which it was found the exudation, as a rule, was not very extensive, and was sero-purulent or fibrino-purulent. These pleurisies, as a rule, even though purulent, eventually resolved, and in those cases which did not resolve there was usually a secondary infection from pathogenic organisms-staphylococci or streptococci. Where streptococci were present an effusion originally serous very frequently became purulent, and when the staphylococcus was present in the serous effusion it could be predicted that that effusion would become purulent. Not many years ago we were taught that many cases of simple serous effusion became purulent as a result of tapping and infection; undoubtedly many of these cases were of the type mentioned, and in which the purulent exudation did not take place until relatively late. Occasionally the effusion would remain serous even when large numbers of staphylococci were present. Pleurisies in which streptococci were found were more commonly secondary and were associated chiefly with acute infectious diseases, such as scarlatina, measles, whoopingcough, diphtheria, broncho-pneumonia, and typhoid fever. They were usually much more serious than the other type.

Aside from the foregoing common forms, other types of micro-organisms were occasionally found. Inflammations in the pleura might be produced by all sorts of other organisms, such as the typhoid bacillus, the Bacillus coli communis, and various saprophytic organisms. Among the conditions in which the organisms tend to produce infectious new growths were tubercle, actinomycosis, gummatous inflammations of the pleura, and, more rarely, leprosy and glanders. The syphilitic form should receive more attention than hitherto. Some of the dry pleurisies attributed to tuberculosis were undoubtedly due to syphilis, and they resolved rapidly under the administration of iodide of potassium, although obstinate to all other treatment. Tubercular pleurisies were now known to be far more common than formerly supposed, some writers going so far as to consider almost all forms of serous pleurisy as due to the action of the tubercle bacillus. In a series of post-mortem cases analyzed by Osler he found tubercles in the pleural membrane in about a third of the cases in which there was pleurisy. When the pleuritic effusion was of tubercular origin it was very likely to be sterile, although occasionally the tubercle bacilli were found in it. It should be borne in mind that the exudation might be either serous, sero-purulent, or purulent, and the process acute, subacute, or chronic, and that when a pleuritic effusion was sterile the presumption was that it was tubercular.

Many observers now believed that all pleurisies were due to new growths, but this view he did not accept.

Some forms, he believed, were due to the action of chemical poisons present in the blood. He thought the pleurisies sometimes associated with chronic Bright's disease were of this variety. He did not regard the pleurisy complicating either acute articular rheumatism or, less frequently, acute gout, as usually due to microbes, but considered it to be due to chemical poisons. This type was also found in various dyscrasiæ—e. g., certain cases of acute hæmophilia accompanied by pleurisy. These pleurisies were apparently the result of a peculiar susceptibility of the pleura to certain chemical substances circulating in the blood, or of a conservative attempt on the part of Nature to eliminate the poison through the pleura.

Pleurisies due to new growths were of two forms: (1) Those secondary to new growths somewhere else, and (2) those where the new growths were primary. The first class was of comparatively little importance, as the history rendered the nature of the trouble sufficiently clear. The second class was more important and was more common than was usually supposed. For instance, where endothelioma occurred the pleurisy partook more of the nature of an inflammatory process in its extent

than of a new growth, and involved the pleura, as a rule, almost uniformly, and was associated with a very abundant effusion at first purely serous, but later on containing some fibrin and after a considerable time becoming sero-hæmorrhagic. In one case which he recalled the patient had been tapped more than twenty times. At first the fluid had been clear, but it had gradually become darker and had contained more blood. Post-mortem examination in such cases showed enormous thickening of the parietal and visceral pleura with nodular growths on the surface of the pleura, and these sometimes extended so as to involve the pleura of the other side and also the pericardium and peritonæum. The structure of the new growth was closely allied to that of carcinoma, containing long tubular spaces, very suggestive of lymph spaces, filled with very large flat cells and bounded by dense stroma. Recent embryological researches seemed to have demonstrated that serous membranes were really allied to mucous membranes and were covered by epithelium instead of endothelium.

Dr. Erdman, referring to the anatomy of the pleura, said that Gray and Holden stated that the pleura extended to the ninth rib on the right side and the tenth on the left side, and posteriorly as far as the twelfth rib. Treves, in his Operative Surgery, 1892, said that very rarely the pleura could be found as low as the twelfth rib, and that it was usually at the tenth. Holden had stated that when a foreign body, such as a bullet, was in the pleural cavity it could be extracted even by cutting below the lower border of the twelfth rib itself. As a rule, the lungs extended down as far as the eighth rib. The surgical landmarks with reference to operative procedures on the chest were taken usually from the lower border of the pectoralis major muscle, corresponding to the fifth rib, and from the first visible interdigitation of the serratus magnus from above, or about the sixth rib. Where there was a simple serous effusion, or in empyema following pneumonia where there was a tendency to go on to resolution, tapping was the proper operation. He recalled the case of a child of two years where thick greenish pus had been removed at two tappings from the pleural cavity, yet the child had recovered in fifteen days and had had no relapse. In cases of purulent effusion not directly traceable to the pneumococcus the operation should be either thoracotomy or this with excision of a portion of one or more ribs-called thoracoplasty, or Estlander's operation. Tapping was done from the sixth to the ninth space, and it was advisable not to go below the ninth space owing to the contiguity of the diaphragm to the chest wall. Thoracoplasty was done in those cases where the effusion was the result of a chronic process, where sinuses existed, or an abscess was pointing-in short, where the condition did not allow of proper expansion of the lung owing to the thickened and rigid pleura. The operation was usually done in the axillary region, and portions of from one to six ribs were exsected. According to Estlander, several transverse incisions were made along the median area of an intercostal space between two ribs; then these two ribs were excised, and this was to be repeated until enough had been removed. The speaker considered the vertical incision the best. It was made in the midaxillary line, the skin was drawn to the side, the muscles were retracted, and the ribs excised. The thickened pleura was then to be scraped and the curdy material removed. The after treatment was simply the usual dressing for an abscess cavity, washing out the cavity only in those cases in which there was a marked odor to the

Dr. H. P. Looms said he had recently examined a number of cases with reference to the line of Ellis and had found some difficulty in mapping out its anterior depression. This line, he believed, was very important as determining whether or not

there was a consolidated lung underneath the fluid. To obtain this line, as he understood it, the lung must be normal and free from any adhesions binding it to the chest wall. This would certainly limit the number of cases to which this test could be applied, for out of 763 autopsies the speaker had found 276, or thirty-six per cent., with lungs bound down by organized adhesions, either general or local, to the chest wall. In all of these 276 cases the lungs had been free from disease except the pleuritic changes; consequently, if fluid had been effused in the pleural cavity of any of these cases, uniform compression of the lungs could not have taken place and the line would have been absent, although there was no disease of the lung itself. Following the Germans, it had been the fashion recently to say that the majority of pleurisies were tubercular, and some even went so far as to say that fully ninety per cent. were tubercular. This was certainly not the experience of observers in this country. Some years ago he had noted, out of a series of nine cases of pleurisy occurring independently of pneumonia or tuberculosis, only two which had been tubercular. Bowditch, of Boston, in a recent article had reviewed his cases of pleurisy for the past thirty years. About ninety cases had been followed up, and it had been found that only thirtyeight per cent. of the patients had died of phthisis. Twice at autopsy and once clinically the effect of pleurisy on the progress of phthisis had been impressed upon him. In the clinical case a man with advanced phthisis had developed pleurisy with effusion, and at once the advance of the tubercular process had been arrested, and for six months the man had gone about attending to his business and enjoying good health, although his chest cavity had been two thirds full of serum. With the idea of getting rid of this fluid, a needle had been introduced and most of the fluid had been withdrawn. From the time he had been tapped the phthisis had progressed very rapidly and he had finally died. In another case seen at autopsy the lung had showed a well marked tuberculosis, and the chest had been filled with fluid. From an examination, it had been evident that the tubercular process had been stopped for quite a while, so that the question arose, Might not pleurisy in phthisis be a conservative process?

Dr. R. J. Carlisle said he had been much interested in Dr. Le Fevre's experiment, yet he thought it would not have much clinical value, because, until the fluid was sufficiently abundant to raise the lung to a high level, it would be difficult to make out the line of the fluid; it could not be made out by percussion except in the axillary line. He understood Dr. Le Fevre to say that if we found the line of flatness in the axillary line, it meant considerable fluid.

Dr. F. M. CRANDALL said he had been interested in Dr. Loomis's remarks about pleurisy and phthisis, for his only case of tapping of the chest which had done badly had been just such a case. The patient had been in fair condition up to the time of the tapping, but he had died in forty-eight hours after the operation. He had seen several cases which illustrated well the natural history of empyema in children. In three, operation was refused, and spontaneous opening had occurred in each at the end of about twenty-one weeks. In these cases there had seemed to be no tendency to cure. This was probably explained by the very late occurrence of the spontaneous opening and the many pathological changes which had occurred before this time. Of these three patients, one had died two or three months after the opening of broncho-pneumonia, probably tubercular; the second one had gone on for three months after the opening, and had finally consented to resection of the rib and curetting, which had resulted in a permanent cure; the third had dragged out a miserable existence for two years, and had finally died of tuberculosis.

For practical purposes, empyema might always be considered secondary. The younger the child, the more complicated the condition. There was usually a certain amount of pneumonia and bronchitis associated with the empyema, and the signs of these conditions obscured the empyema. Bronchial respiration was almost always heard. When this was audible from the top to the bottom of the chest, it was a good sign of fluid. Percussion was sometimes misleading, for over the condensed lung there was often tympanitic resonance. When over the area where fine rales had been heard from day to day the respiratory signs became absent, it was very significant of fluid.

Dr. J. M. Byron said that a number of years ago he had had an opportunity of making some experiments with dried and recent tubercular sputum in guinea pigs, and he had found that those inoculated with the dried sputum would resist a great deal longer the action of the tubercle bacilli than those inoculated with fresh sputum. He had thought that the retraction of the lung caused by the pressure of the fluid in the cavity might explain this, and experiments which he had made in this direction had been published about seven years ago. Each organ had two modes of activity-functional and metabolic. If only metabolic activity of the organ were affected, it would simply be deprived of a portion of its nutriment; if its function were impaired, its restoration could be aided by diminishing the functional activity. Thus, in the early stages of tubercular joint disease, immobilization would stop the process; in other words, by depriving it of its functional activity, its metabolism had been increased. In this way we simply aided Nature to do what she would do if she could. Similarly an effusion into the pleural cavity might, by restraining its functional activity, increase the amount of nutriment sent to that organ, and so aid materially in arresting the tubercular process.

He agreed to the classification given by Dr. Biggs, except as regarded considering every effusion as pleuritic. Our medical nomenclature was much confused. The cases of endothelioma of the pleura he did not consider true pleurisy any more than he considered the proliferation of pus corpuscles in the pleural cavity produced by the presence of actinomyces a pleuritis. Five or six years ago he had presented to the society a remarkable case of resection of the ribs in a boy who had apparently had a primary purulent pleurisy. An incision had been first made, but, as the empyema had continued, portions of eight ribs had been excised, the periosteum being left. The boy was still living.

Dr. J. E. Winters said, with reference to the natural history of empyema, that the remarks of Dr. Crandall gave a clear idea of what should be the treatment of a case which had opened spontaneously or was about to do so. In every such case a counter-opening should be made posteriorly at the point where the opening was ordinarily made when there was no spontaneous opening. In cases of empyema where the opening had taken place internally into a bronchus the same treatment was demanded, for, although a number of cases of recovery had been reported where an internal opening had occurred, the majority of these had ended in tuberculosis. It seemed to him that most of the empyemas met with in children occurred in connection with or immediately following pneumonia, and it allowed to run their natural course they would end as already stated. A few years ago he had thought that he was going to have two recoveries after aspiration in empyema; however, one of the patients had eventually died of tubercular meningitis, and the other now apparently had phthisis. The results of operation for empyema in children were so satisfactory that it seemed to him useless to adopt any other treatment than a free external opening. A good result almost invariably followed simple incision without excision of a rib. One of the reasons for failure

to get complete recovery after simple incision and drainage was that the incision was not made sufficiently free; it should be at least two inches long and should not be made too low down when the diaphragm was much depressed. The temptation was to open at the lowest point, but it seemed to him that the opening should always be at the same point, regardless of the depression of the diaphragm. If the incision was made too low, after retraction of the chest wall had begun, there would be a temporary retraction of the diaphragm, and this would cause occlusion of the opening and defective drainage. The incision should be made just above the level of the normal percussion resonance on the sound side. After making a free incision care should be taken to completely empty the abscess, and, if the patient's condition admitted of it, he firmly believed that the pleural cavity should be washed out, the consensus of opinion to the contrary notwithstanding. Nearly always there were large collections of fibrinous pieces which could not be removed except by free incision aided by flushing of the cavity. Complete recovery could not occur unless such irrigation was done. After once thoroughly flushing the cavity it was scarcely ever necessary to repeat the irrigation. It seemed to him that Estlander's operation was only applicable to neglected cases of empyema or where there was great rigidity of the chest walls or a thoracic fistula. He had operated altogether over sixty times by the method just described, in every instance without excision of a rib, and all the patients had recovered notwithstanding that many of them had been dispensary patients with bad surroundings.

Dr. Winters then exhibited several of the patients on whom he had operated for empyoma.

Dr. Le Fevre said that the demonstration he had made was not original with him, but had first been brought before the profession by Garland, of Boston, in his work on Pneumonodynamics. If we found the curved lines of Ellis, it showed that the lung was normal in elasticity or retractile power; if, on the other hand, at an early stage this line did not follow that curve, we knew the retractile power of the lung had been impaired, and this pointed to tubercular infiltration, emphysema, or adhesions of the lung to the chest wall. Again, the point of greatest distention and elasticity in the lung was in the lower portion in the axillary line. Garland's experiment of injecting cacao butter into the pleural cavity of a dog showed that quite early the line of dullness appeared in the lower axillary region; hence this zone of flatness was an early diagnostic point. This zone had been mistaken for an enlarged spleen.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of January 23, 1894.

The Opium Disease in Infants and Children,-This was the subject of a paper by Dr. Louis Fischer, who expressed the belief that the disease was much commoner than was generally supposed; some cases diagnosticated as marasmus or as summer diarrhœa were really cases of opium poisoning. Ignorant mothers and monthly nurses were generally responsible for the administration of the drug. One mother had bought opium of a Chinaman and given it to her child in half-grain doses. Another had administered as much as six tablespoonfuls of paregoric at a dose. The liability of children born of opium-eaters to die of collapse if the drug was withheld after birth was commented upon. The symptomatology included diarrhea, sometimes alternating with constipation, loss of appetite, irritability, restlessness, sleeplessness, almost constant stupor, itching, as indicated by scratch marks, rapidity of the heart's action, decided sweating, scantiness of the urine, which was sometimes

albuminous, and occasional vomiting—all this without fever. Besides sulphonal, which seemed to bold the first place in the treatment, brominated camphor, lupulin, chloral, and potassium bromide had been found useful. It was greatly to be deprecated that paregoric could be bought so readily without a prescription and without labels to indicate the doses proper for children of various ages.

Puerperal Sepsis; its Prophylaxis and Treatment.-Dr. ROBERT A. MURRAY read a paper with this title. Antisepsis during labor, he said, was believed to be as necessary as in surgery. Three antiseptics could be managed easily-corrosive sublimate, carbolic acid, and creolin. The prophylaxis should begin with a bath and a change of clothing. The vulva especially should be cleansed carefully. A new rubber cloth should be spread over a clean sheet, and over the rubber there should be a draw-sheet. The importance of an enema should not be forgotten. A vaginal injection of a 1-to-3,000 solution of corrosive sublimate or of a two-per-cent, solution of creolin should be given before labor, but usually not after it. Creolin was to be preferred to corrosive sublimate, because it was something of a lubricant, while corrosive sublimate was distinctly astringent, and so facilitated laceration. An antiseptic pad and napkin should then be applied, and never removed except for examination, which should not be more frequent than was actually necessary. The physician's hands should be scrubbed thoroughly and immersed in a 1-to-2,000 solution of corrosive sublimate or a two-per-cent. solution of creolin. The antiseptic pad should be applied again after the birth of the child and before the expulsion of the placenta. Retained membranes and pieces of placenta should be removed at once by the aseptic hand, and then an intra-uterine douche should be given. Fluid extract of ergot, in half-drachm or drachm doses, was to be recommended in the majority of cases. After urination an antiseptic solution should be applied. When there was a bad odor to the discharge a vaginal douche was to be ordered, but if the examining finger showed that the foul discharge came from the uterus, it must be thoroughly curetted and a single intra-uterine douche given. In prolonged cases instruments were to be employed. The nurse should never be allowed to examine a patient. In case of sepsis, the same general plan of antisepsis should be followed, but the vagina ought to be inspected so that diphtheritic membrane might not be carried into the uterus.

# Book Antices.

Dissections Illustrated. A Graphic Handbook for Students of Human Anatomy. By C. Gordon Brodie, F. R. C. S., Senior Demonstrator of Anatomy, Middlesex Hospital Medical School, etc. With Plates drawn and lithographed by Percy Highley. In Four Parts. Part I. The Upper Limb. With Seventeen Colored Plates, two thirds natural size. Pp. iv-34. Part II. The Lower Limb. With Twenty Colored Plates, two thirds natural size, and Six Diagrams. Pp. 36-74. London and New York: Whittaker & Co., 1894. [Price, \$4.50.]

This is an admirable series of lithographic plates for use at the dissecting table, accompanied by a small amount of explanatory text. The structures are represented as of three fourths the natural size, but yet the book is not so large as to encumber the student. Each part should be bound separately in enameled cloth, as is now the excellent custom for dissecting manuals. The work follows the

usual plan of English works of this character in leaving the student without definite instructions for exposing the parts represented. Its value would be greatly enhanced if an introduction were furnished describing the necessary instruments and their care and use, and if under each dissection concise directions for its preparation were given. The French manuals, like that of Morel and Duval, are far superior in this respect to any existing English ones.

The diagrams appear to be by a different hand and are by no means as well drawn as the plates. The simplified form of the brachial plexus that accompanies Plate III could have been still further simplified to advantage had Rauber's method of the formation of three cords which interunite by anterior and posterior branches been followed. The ancient method of showing the cutaneous distribution of nerves by straggling filaments rather indefinitely distributed might have been superseded to advantage in so fine a work as this by diagrams like those of Heiberger indicating the cutaneous areas by distinct colors.

A System of Genito-urinary Diseases, Syphilology, and Dermatology. By Various Authors. Edited by Prince A. Morrow, A. M., M. D., Clinical Professor of Genito-urinary Diseases, formerly Lecturer on Dermatology in the University of the City of New York, etc. With Illustrations. In Three Volumes. Vol. II, Syphilology. New York: D. Appleton & Co., 1893. Pp. xvii-917.

The second volume of this already well-known work treats of syphilology in its entirety.

The collaborators have been selected with regard to their special fitness to deal with given subjects, and they have done their work conscientiously and well. The book opens with a chapter on the History, Geographical Distribution, Evolution, and General Pathological Anatomy of Syphilis, by Dr. J. N. Hyde. The writer does not believe in its prehistoric existence, but confines the disease, as we know it, to the period succeeding the fifteenth century, notwithstanding recent researches into Chinese history show the malady to have existed in that country long before that period. As to its geographical distribution, he says "the propagation of syphilitic disease respects, indeed, neither national boundaries, geographical divisions, nor the isothermal lines drawn across earth and sea." The ordinary meaning of the term "variant," used on page 37, would indicate that the author believed syphilis, leprosy, sarcoma, epithelioma, etc., to be instances of normal histogenesis. He certainly meant variations.

The Ætiology of Syphilis is treated of by Dr. John A. Fordyce in a forcible and thorough manner. He concludes that, notwithstsnding "many important conditions are necessary to prove that syphilis is caused by the bacillus of Lustgarten," there are evidences sufficient to justify the conclusion that it must have some ætiological connection with the disease.

Under Modes of Infection in Syphilis, Dr. Bulkley gives expression to his belief in inoculation by conception from mother to child and vice versa, and also through the semen.

In the article on Constitutional Syphilis Dr. Zeissler describes as unusual prodromes painful swellings about the head and clavicle, effusions into the joints, enlargement of the spleen, hepatic icterus, and albuminuria. These conditions are certainly rare in the early stages of the disease, and seem to us rather evidences of precocious syphilis in which the secondary and tertiary lesions develop simultaneously. Gummata, periostitis, and nervous lesions have been seen to develop at the same time or even before the cutaneous manifestations. They are not prodromes, but distinct later lesions produced at this early period by the profound intoxication of the individual.

The writer states an important fact when he says that, under proper aseptic precautions, surgical wounds heal just as well in the syphilitic as in the non-syphilitic. Although in profound syphilitic cachexia this is not the case, it should be understood that here we have to deal with general deterioration of the system, and not with the influence of the specific virus. Nevertheless, the fact remains that syphilitic lesions themselves will not bear traumatism without suppuration, and wounds of the mucous membrane, which in the healthy would heal spontaneously, in the syphilitic suppurate, slough, and spread. This, as the author says, is no doubt due to the fact, pointed out by Neumann, that months after the disappearance of cutaneous manifestations there is still cell infiltration around the capillary blood-vessels, and irritation will stimulate these deposits into renewed activity.

To those who have seen Dr. Morrow's Atlas of Syphilis and Skin Diecases it is unnecessary to say anything of his article on Syphilodermata in the present work. The same conscientious care and original study are evinced throughout the chapter as in that work. If this volume had nothing else in it, that would be its sufficient raison d'être.

It would be a pleasure to notice each of the articles in this interesting volume, but lack of space forbids. That by Dr. W. R. Townsend on Syphilitic Affections of the Bones deserves special notice. When one comes in contact with these serious manifestations of hereditary syphilis, and realizes that many of them develop in children whose parents never knew they had the disease, or supposed they were cured of it, it makes us hesitate to assure any one with even a suspicious history of his fitness for marital relations. That the disease is curable we have no doubt, but to say when it is cured is most difficult.

Under the head of Syphilis of the Genito-urinary System Dr. Fuller gives a most interesting account of syphilis of the kidney. This appeals particularly to the general practitioner, who is more apt to be consulted concerning the symptoms of this disorder than the specialist.

Dr. Armstrong gives an exhaustive paper on Syphilis in Relation to Public Health. After a careful analysis of extensive statistics he concludes that the disease is not increasing in the United States, and that the only feasible plan for limiting it is for the hospitals to open their doors for the free treatment of all infected persons, and thus make it possible for those to be cured who are most apt to disseminate the disease.

Considering the number of writers for this volume, there is remarkably little repetition in it. No doubt this is due to the watchful care of Dr. Morrow, whose editorial work upon the book deserves the highest commendation.

The mechanical work upon this volume is a specimen of the highest type of the printer's art. The plates are numerous and embrace some made by new processes which promise radical departures in illustrating medical subjects requiring two or three colors.

As a whole, the work deserves the highest praise, and any one possessing it may be assured that he has the most and best of what is known about sypbilis.

A Practical Treatise on Materia Medica and Therapeutics.
By Roberts Bartholow, M. A., M. D., LL. D., Professor of
Materia Medica, General Therapeutics, and Hygiene in the
Jefferson Medical College of Philadelphia, etc. Eighth
Edition, revised and enlarged. New York: D. Appleton
and Company, 1893. Pp. xxvii-820. [Price, \$5.]

The first edition of Dr. Bartholow's work on *Materia Medica* appeared in 1876, and since that time the great favor with which it has been received by the medical profession, to-

gether with a desire that it should keep pace with advances in pharmacology and therapeutics, has led to the production of seven revised editions. The last edition conforms to the recent revision of the *Pharmacopxia*, and also contains matter upon the more recent drugs which, while not official, are yet in daily use and, many of them, of considerable importance.

The wisdom of introducing these non-official drugs we think must be self-evident, for, though a book of this kind must be based upon our official standard, the *Pharmacopaia*, yet, as the author says, the necessarily great conservatism of the latter is not required of the former, especially in the consideration of the newer drugs which have come into such extended use and upon which information is so important. The character of the book remains, as always, one of careful arrangement and much completeness, and the work is of the greatest practical importance and usefulness. Indices, both clinical and remedial, are added, as well as tables of metric equivalents.

A Text-book of Physiology. By M. Foster, M. A., M. D., LL. D., F. R. S., Professor of Physiology in the University of Cambridge, etc. With Illustrations. Sixth Edition. Part I, comprising Book I. Blood. The Tissues of Movement. The Vascular Mechanism. New York and London: Macmillan & Co., 1893. Pp. 387. [Price, \$2.60.]

It is but a short time since we noticed the final part of the fifth edition of this work, and even then the author was preparing for the sixth edition. There are few changes in this edition except in the chapter on the vascular mechanism, in which the author has introduced descriptions of Hürthle's membrane manometer, of Roy's and Adams's cardiometer, and of Stolnikow's method of determining the quantity of blood ejected by the right ventricle. Attention is called to the facts not only that the quantity of blood ejected at the systole may vary from time to time, but also that at times, if not normally, the whole of the blood present in the ventricle at the systole may fail to leave the ventricle during the systole, so that the ventricle is incompletely emptied. Again, the ventricle may discharge its contents in the earlier part of the systole and remain contracted for some little time after it has emptied itself. Some other minor facts similar to these constitute the only additions.

### BOOKS, ETC., RECEIVED.

The National Dispensatory. Containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicine, including those recognized in the Pharmacopæias of the United States, Great Britain, and Germany, with Numerous References to the French Codex. By Alfred Stillé, M. D., LL. D., Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania; John M. Maisch, Phar. D., late Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy; Charles Caspari, Jr., Ph. # Miscellany.

The Forcible Feeding of the Insane,—In the *British*Medical Journal for January 27th Dr. James Neil, of the
Warneford Asylum, Oxford, recommends the following method:

"(a) The food must be liquid; custard of egg and milk is a very good and convenient food. But it is desirable, especially if the feeding has to be kept up for any length of time, to have some variety, and to introduce the vegetable element. We begin by giving a couple of eggs in a quart of new milk, morning and evening. For dinner about the middle of the day, a ration of meat pounded fine in a mortar, with two or three good-sized potatoes, and added, along with a couple of eggs and a cupful of cream, to the liquor in which the meat was boiled, the whole being made into a smooth purée with all solid particles strained off. If this last point is not attended to, the feeding tube will be choked, and an awkward interruption to the operation caused. It will be observed that all

the elements of the meat are retained, which is not the case with ordinary beef tea. The potatoes should be cooked by steaming, or boiled in their skins, so that the vegetable salts are not lost. To each of these three meals a dose of cod-liver oil should be added, gradually increased to a tablespoonful. If symptoms of exhaustion are at all marked, from half an ounce to an ounce of brandy should also be added. If, after a week of this regimen, the body weight is still falling, another egg must be added to each meal.

"(b) The room in which the operation is performed must be well lighted. Place a mattress on the floor, in the full light of the window, and lay a pillow on the end of the mattress farthest from the window. Have a yard all around the mattress clear of furniture.

"(e) Instruments: 1. A feeding tube. It should be of flexible material, as thick as a smallish finger, and soft to the very tip. No part should be hard or rigid. An accident can hardly happen with such a tube. It is too large to enter the laryux, and too soft to perforate the stomach or esophagus. It is best to have the cup for receiving the food made in one piece with the tube, and of the same material. 2. A screw gag of plated metal, thin at the tips, and serrated to prevent it from slipping off the teeth. 3. A small bottle of olive oil. 4. A counterpane folded double. A counterpane is better than a sheet, because, being thicker and softer, it lies more closely to the patient's body, and prevents movements more effectually. 5. A towel. 6. The food, in a jug with a handle and spout; not a basin. If a basin is used, much of the food will be spilled as it is being poured into the funnel.

"(d) To prepare the patient: Take off the boots, and loosen the clothing about the body and neck. In the case of a woman, direct the nurse to unfasten the stays and slacken the petticoats.

"(e) The operation: Four assistants are required-one at the head, one at the feet, and one at each side. The patient is made to stand on the mattress, near the window end, with his face to the light. The chief assistant stands close behind the patient, and puts his arms through the armpits of the latter. Those at the sides grasp the arms of the patient at the wrist with one hand, and at the elbow with the other. The assistant at the feet, standing at one side, puts his arms around the patient's ankles and snatches his feet from under him, while the others, especially the chief assistant, support the body and let the patient gently and quickly down on the mattress on his back, the feet being toward the window and the head on the pillow. The light must fall on the patient's face. The operator throws the doubled counterpane across the patient's body. covering him from the shoulders to the waist, the arms being under the counterpane and close to the sides. The chief assistant takes the head firmly between his knees, kneeling behind the patient, the back of whose head rests on the pillow. The second assistant kneels astride the patient's legs, and grasping the knees with his hands, presses them downward. Those at the sides kneel on the loose ends of the counterpane close to the patient's body, grasp the elbows with one hand and the wrists with the other through the counterpane, and press downward on the mattress. In this way the patient is completely controlled in a few seconds, and a prolonged struggle, causing terror and exhaustion, is impossible. The chief assistant tucks the towel under the chin to prevent the clothes being soiled.

"Here a caution must be given. The assistants must on no account kneel on the patient or grasp the bare wrists. That must be done through the counterpane or the sleeve of the coat or dress. The chief assistant who holds the head must not squeeze the ears between his knees. The need for these

precautions will be evident when it is remembered how easily many of the insane are bruised.

"The operator now kneels at the right-hand side of the patient's head, and places the instruments and vessels on the floor at his own right hand. He oils the tube and lays it across the patient's chest, on the towel, to be ready. The oil should not be omitted, for, as has already been said, the œsophagus is in a dry condition, the secretion of mucus being in abeyance. Then he inserts the gag between the molars, and opens the mouth widely with the screw. If the patient clinches his jaws, there are, in most cases, irregularities or gaps between the teeth that will admit the gag, or the nostrils may be pinched between the finger and thumb, when the patient will probably open his mouth for a moment to breathe, or he may be surprised into speaking by asking him a question suddenly and sharply. If these means fail, we can generally slip the gag in gradually by keeping a steady moderate pressure with it for some time. When the mouth is well opened, the operator passes the gag to the chief assistant, who holds it in position with his right hand, taking care that it does not turn round, or slip forward out of the mouth. The operator then takes the oiled tube with his left hand near the cup end, and with his right about eight inches from the point. Introducing the point into the pharynx, he guides it gently down the gullet into the stomach. The stomach is known to be reached by the feeling of resistance ceasing, and by a puff of gas that comes through the tube with a slight gurgling sound. The ear should be inclined toward the tube to catch this indication. Occasionally the point hitches against the back of the pharynx, the tube doubles forward at its weakest part—where the eyes are pierced, namely—and, pressing against the larynx, causes violent dyspnœa. This is apt to happen when the head of the patient is too far extended, causing the cervical vertebræ to bulge forward. Withdraw the tube and direct the chief assistant to flex the head. Reintroduce the tube, and, with the right forefinger in the pharynx, guide the point into the esophagus. Sometimes there is a spasmodic action of the gullet, and the tube is grasped by it. Hold the tube against the obstruction for a few seconds, when the spasm will relax and the tube will pass down. Then, holding the tube upright with the left hand, with the right pour the food into the cup as fast as it will go down. If the flow is checked, it is because the eyes of the tube are closely applied to the gastric mucous membrane and are thus blocked, or because the tube is doubled in the stomach. Withdraw the tube for a couple of inches, and the food will flow. In some cases there is much regurgitation of food, causing troublesome, or even alarming, symptoms of suffocation. Lay down the jug and suspend the administration of food by pinching the soft stem of the tube with the right forefinger and thumb till the regurgitation subsides, then go on again. It may be necessary to do this two or three times in the course of the operation. When all the food is given, withdraw the tube gently, keeping it, while doing so, toward the roof of the mouth to avoid tickling the epiglottis. The patient is then released. It is usual to allow him to lie for a short time to lessen the risk of vomiting, but that accident rarely occurs. The operation now described can easily be performed, when the assistants are expert, in four minutes and a half from the time the patient is placed standing on the mattress till the moment he is released. This is an important point in favor of the method, for, in the most favorable case, the mind and the muscles of the patient are held in a state of painful tension, and when there is exhaustion, regurgitation of food, and alarming symptoms of choking, forcible feeding is a disagreeable and anxious operation. It is almost as much so in fact as the giving of an anæsthetic, and the more quickly it can be performed the better."

The Use of Organic Extracts.—In the February number of the Edinburgh Medical Journal there is an article on this subject, by Dr. R. W. Felkin, in which we find the following passages:

"With regard to the way in which these organic extracts act, I am not prepared at the present time to offer any opinion, but it is evident, from what we know of the administration of thyreoid extracts in myxeedema, that they can act very powerfully. I believe also that organs such as the ovaries and the testicles possess the power of elaborating an internal secretion, as it is termed by Brown-Séquard, which is perhaps not absolutely necessary, but, at any rate, of importance to the organism."

The author then gives brief notes of a number of cases of nervous disease in which he has used the extracts, and adds:

"I believe that I have hit upon a plan of treatment which will be of considerable use in a different class of cases. The cases I refer to are those of patients suffering from ovarian disease or other nervous disease connected with the genital system.

"Before mentioning any cases or referring more specially to the method of employing the orchitic extract—for that is what I have used—I want to make a few very brief remarks as to how I came to take an interest in this matter.

"I think that it is quite possible sometimes to obtain hints as to treatment from primitive people. In 1879 I had the opportunity of becoming acquainted with many of the habits and customs of Central African natives, and also of conversing with Easterns of various races. It might be interesting, but I doubt if it would be profitable, were I to detail the exact practices which I met with. It is sufficient to say that on various occasions I found that human semen was administered to debilitated patients with wonderful success.

"Naturally this made some impression upon me. I also found that the natives were in the habit of devouring the raw testicles of animals, owing to their supposed strengthening properties; and still further, that during the slave wars it was the custom for both Arabs and natives to perform the most disgusting acts of cannibalism with a view to obtaining increased prowess.

"Knowing this, it has occurred to me that Brown-Séquard is quite right in stating that the internal organs do not only elaborate a fluid for excretion, but also a product which is necessary for the mental and physical well-being of the individual. From this I have been led to imagine, first, that the ovary elaborates a product which is necessary for the well-being of the woman; and, secondly, that the orchitic fluid is not solely intended to fertilize the female, but that it also contains a substance which, although not necessary, is beneficial. It may be that it allays the orgasm in the female among other uses.

"If these ideas be true, they explain certain diseased or morbid states which one meets with in practice, and they also, I think, give a hint as to how we may deal with such unhappy cases when we do meet with them. Certain experiments which I have been able to make seem to show that I am right, and I mention them because I am anxious that my ideas should have a more extended trial than it is possible for me to give them. I have no hospital ward in which to make experiments, and in dispensary work one does not meet with such cases very frequently, and one needs to have a very large practice to gain sufficient scope for setting the matter at rest in the only practicable way—namely, by trial.

"The first class of cases to which I will refer for a moment is that in which the ovaries have been removed. Now, this operation is performed for two reasons—either because the

ovaries or tubes are themselves diseased or because it is hoped to cure hysteria or some other such-like nervous condition. To take the latter cause first. As far as I am able to read, the operation does not appear to be very successful, and even in the most successful hands the patient is exposed to a risk. Now, I fancy that were either cerebral extract or orchitic extract administered, in a considerable number of these cases cure would result; and in two cases, one of which was grave hysteria, the other mental instability and nymphomania, I have, I believe, been successful in inducing a cure. In both cases orchitic suppositories were employed. In another case of a somewhat similar character-namely, where in commencing puberty in a girl aged seventeen, a delicate, anæmic, highly excitable girl, the onset of the menstrual function was accompanied by intense excitability and loss of self-control, which almost rendered restraint in an asylum necessary-cerebral extract acted very beneficially.

"In those cases where the ovaries have been removed for disease certain evils may ensue. For my purpose I need only mention grave melancholia and hyperchondriasis. I think that the administration of an organic extract may be of considerable service. At any rate; in one case at the beginning of this year, in which a patient who had had her ovaries removed suffered from severe melancholia, it was successful; and in another case which I attended more recently the results were somewhat curious. A. P., aged twenty-two, came to me suffering from depression, accompanied by thoughts of suicide and an alteration in her voice. She had been to various throat specialists on this account and had been told by her employer that she must give up her position unless she was soon cured. Her ovaries had been removed eighteen months ago. She recovered well from the operation and went on satisfactorily for more than a year, and it was only at the beginning of this year that her trouble commenced. I hardly thought I should be able to do any good in this case, but it was a chance not to be missed. She took a month's holiday. I put her upon large doses of cerebral extract, which she seemed to appreciate; at any rate, she gained weight-rather more than a stone in a month; she lost all her gloomy fears and her voice has returned to its former pitch."

Should Physicians Charge Each Other for Medical Services ?- "In view of the almost universal custom of physicians, as well as of the tradition of the profession, the question," says the Medical News, "would seem to be almost insulting. Nevertheless, there are a number of physicians who would answer the question affirmatively, and others who would not say No with quite the emphasis to be expected. The question was lately asked of a prominent and highly respected physician, and his answer was that, while no honorable physician, without demand, would name a charge or send a bill to a brother physician, it is growing more and more customary for the recipient of the service to demand the bill. There is, perhaps, something to be said upon this side of the question. In default of a money payment, the grateful patient will naturally make his physician some gift, but he finds it difficult to select a suitable present; it makes him, apparently, a useless trouble, and he keeps thinking that his physician might as well take the money and spend it more to his own liking. In obstetric cases, in prolonged illness, or other work wearying or expensive, whether to life or pocketbook, certainly no physician would permit his benefactor to go without some more substantial reward than the most sincere gratitude. The result of the tendency to put the service on a financial basis would, however, lead easily to abuse, and would likely soon destroy that largeness and lovableness of spirit, that mutual helpfulness and

esprit de corps that has been one of the most delightful and enheartening characteristics of the medical guild. Such a cloud over the medical landscape would give it a very different tone from what it has heretofore shown, and, we are happy to say, which it still exhibits. Nothing so robs a man of respect, nothing sooner surrounds him with an atmosphere of concealed contempt, nothing more speedily deprives him of professional skill or usefulness, than the basing of every act on the hidden thought of 'How much money can I get out of it?' A surgeon once performed an operation on a physician's wife, and took occasion during convalescence to ridicule the offering of a small gratuity sent him for a similar service by another physician, as well as otherwise hinting the money value of his work, and this despite the bistory of many 'reference cases' from the lady's husband to the surgeon. However large the fee got by such means, it was, as we all know, stupidly poor policy and worse principle. The very air about such a man shrinks from him."

The Life-insurance Agent and the Doctor.—The following verses, by Dr. Henry S. Durand, of Rochester, were read at the recent annual dinner of the Medical Society of the State of New York:

Father Time he plays the fife
For this march of modern life
With a quickstep, and the hustler is our proctor;
And amid the jostling throng
Which is hurrying along
Go the life-insurance agent and the doctor.

The life-insurance agent
Declares that life's a pageant,
And reminds us that its ways are growing rougher;
And with motives all most pure
He entreats us to insure,
That when we die our families may not suffer.

He buttonholes the youth,
And, with looks of earnest truth,
He talks from early morn until the gloaming;
Till be makes him quite agree
That a Toutine policy

Is better than a gold mine in Wyoming.

He shows him 'tis an error
To feel for death a terror,
Since insurance makes its cup as sweet as honey;
One may die without chagrin,
Or live for years and win—
Whichever you may choose, you get your money!

He corners aged men
Nearly threescore years and ten,
And when their waistooat button he has pressed
For half a day or more,
He leads them to the door
Of the doctor, for the doctor does the rest.

But when he gets them there
Is his visage free from care?
No, it's anxious, though he strives to make it placid;
For most truly does he know
That his man must undergo
The crucial test of heat and nitric acid.

He knows that clouds may rise
On most propitious skies—
Those fleecy clouds the doctor calls albumen;
He knows the stethoscope
May quickly dash his hope
By the murmurs which may whisper through its lumen.

Sometimes the doctor's lazy,
And, though the glass be hazy,
He sees it not; nor will be time devote
To seek for an impediment
Among the scanty sediment
Nor scan the test-tube held against his coat.

His stethoscope is pressed
On a chest that's fully dressed,
Of what he hears he has not e'en a notion;
And so the man is passed,
Though his kidneys have lost cast
And his heart may murmur like the summer ocean.

And yet what does it matter
If invalids they flatter
And make them half believe that they are healthy?
The doctor gets a V,
The man a policy,

And the agent—well, the company is wealthy.

And when the man is dead,
And o'er his honored head

And o'er his honored head
A stone is raised with epitaph upon it—
His widow's sable weeds,
By the underwriter's deeds,
May change to blossoms on an Easter bonnet,

The Congress of American Physicians and Surgeons.-The officers of the congress, which is to be held in Washington on May 29th, 30th, and 31st and June 1st, are as follows: President, Dr. Alfred L. Loomis of New York; vice-presidents, ex officio, the president of the American Ophthalmological Society, Dr. George C. Harlan, of Philadelphia, the president of the American Otological Society, Dr. Gorham Bacon, of New York, the president of the American Neurological Association, Dr. B. Sachs, of New York, the president of the American Gynæcological Society, Dr. William T. Lusk, of New York, the president of the American Dermatological Association, Dr. Robert B. Morison, of Baltimore, the president of the American Laryngological Association, Dr. D. Bryson Delavan, of New York, the president of the American Climatological Association, Dr. Andrew H. Smith, of New York, the president of the Association of American Physicians, Dr. Reginald H. Fitz, of Boston, the president of the American Association of Genitourinary Surgeons, Dr. George Chismore, of San Francisco, the president of the American Orthopædic Association, Dr. A. M. Phelps, of New York, the president of the American Physiological Society, Dr. Henry P. Bowditch, of Boston, the president of the Association of American Anatomists, Dr. Harrison Allen, of Philadelphia, the president of the American Pædiatric Society, Dr. James H. Keating,\* of Colorado Springs, the president of the American Surgical Association, Dr. J. Ewing Mears, of Philadelphia; chairman of the executive committee, Dr. Landon Carter Gray, of New York; treasurer, Dr. John S. Billings, of the army; secretary, Dr. William H. Carmalt, of New Haven.

The meetings of the congress will be held in Metzerott's Music Hall, corner of Twelfth and F Streets, N. W. The preliminary programme is as follows: Tuesday, May 29th.—3. P. M.: Congress opened by the chairman of the executive committee. From 3.30 to 5 P. M.: General session of the congress under the direction of the Association of American Anatomists, Wednesday, May 30th.—From 2 to 3.30 P. M.: General session of the congress under the direction of the American Climatological Association. From 3.30 to 5 P. M.: General session of

the congress under the direction of the American Dermatological Association. 7 P. M.: Dinner to the guests of the congress at the Arlington Hotel. Thursday, May 31st .- From 2 to 3.30 P. M.: General session of the congress under the direction of the American Association of Genito-urinary Surgeons. From 3.30 to 5 P. M.: General session of the congress under the direction of the American Gynæcological Society. 7.30 P. M.: Address by the president of the congress, Dr. Alfred L. Loomis, on The Influence of Animal Experimentation on Medical Science. To be followed by a reception. Friday, June 1st .- 1.30 P. M.: Business meeting of the congress. From 2 to 3.30 P. M.: General session of the congress under the direction of the American Laryngological Association. From 3.30 to 5 p. m.: General session of the congress under the direction of the American Neurological Association.

Subjects for Discussion .- By the Association of American Anatomists: Morphology as a Factor in the Study of Disease. Opened with a paper by Dr. Harrison Allen, and discussed by Dr. Thomas Dwight, Dr. Frederic H. Gerrish, Dr. Frank Baker, and Dr. Burt G. Wilder. By the American Climatological Association: Sewer Gas. The Bacteriology, by Dr. Alexander C. Abbott; As a Cause of Disease, by Dr. Abraham Jacobi, By the American Dermatological Association: The Distribution and Control of Leprosy in the United States. The Distribution. Opened with a paper by Dr. J. Nevins Hyde, and discussed by Dr. W. A. Hardaway and Dr. James E. Graham; The Prophylaxis and Treatment, with a paper by Dr. J. C. White and discussed by Dr. George H. Fox, Surgeon-General W. C. Wyman, U. S. M. H. Service, and Dr. Joseph D. Bryant. By the American Association of Genito-urinary Surgeons: Nephritis in its Surgical Aspects. Opened with a paper by Dr. Edward L. Keyes, of New York, followed by a paper by Dr. George M. Sternberg, Surgeon General of the United States Army, on The Bacteriology of Nephritis, and discussed by Dr. George Chismore, of San Francisco, Dr. L. Bolton Bangs, of New York, Dr. Francis S. Watson, of Boston, and Dr. W. N. Wishard, of Indianapolis. By the American Gynæcological Society: The Conservative Surgery of the Female Pelvic Organs. Papers will be read by Dr. W. M. Polk and Dr. W. Goodell. By the American Laryngological Association: The Surgery of the Accessory Sinuses of the Nose. To be discussed by Dr. F. H. Bosworth, of New York, Dr. J. N. Mackenzie, of Baltimore, Dr. J. H. Bryan, of Washington, Dr. J. O. Roe, of Rochester, and others. By the American Neurological Association: The Influence of Infectious Processes on the Nervous System. Pathology and Ætiology, by Dr. J. J. Putnam, of Boston; The Relation to General Nervous Diseases, by Dr. E. C. Seguin, of New York; the Relation to Mental Disease, by Dr. Charles K. Mills, of Philadelphia; and The Therapeutics, by Dr. F. X. Dercum, of Philadelphia.

Hypnotics.-At a recent meeting of the Paris Société de thérapeutique, a report of which is published in Le Mercredi médical for January 31st, M. Bardet read a paper on the comparative value of hypnotics. The ideal hypnotic, he said, was one that would produce sleep without unpleasant accompaniments or consequences. After passing in review a class of hypnotics of which morphine was the type, and in which the hypnotic effect was doubled by an anæsthetic action, the author made a critical comparison of drugs which, like sulphonal, produced sleep without anæsthesia, somewhat analogous to that caused by alcohol, and had the advantage over chloral of not irritating the digestive organs. In this class of hypnotics he placed paraldehyde, which acted, he said, like alcohol, and this fact would perhaps explain the excellent results of its administration to persons addicted to alcohol. Methylal, in spite of

the evanescence of its action, was greatly superior to chloral in that it caused no unpleasant feelings after sleep and had no irritative action. He advised its use more particularly with women and children. The last group of hypnotics considered by the author was chloral and its derivatives. These he classed as energetic hypnotics, but chloral, he said, had the drawback of giving rise to a disagreeable feeling of heaviness after sleep; moreover, it irritated the digestive canal and sometimes occasioned cutaneous erythema. The derivatives of chloral, such as chloralamide, chloralose, chloralantipyrine, etc., were free from this irritative action. By a minute study of these derivatives M. Bardet had been led to the conclusion that it was only the chloral in them that exerted the hypnotic action, and a powerful argument in support of this opinion was the fact that the chloralic compounds produced sleep only when they were given in sufficient quantity to contain an active dose of pure chloral. The volatile hypnotics, he added, were capable of producing rapid results without affecting the digestive canal,

M. Paul thought that M. Bardet's researches had been physiological rather than therapeutical. In order to be serviceable to the practitioner it would be necessary to study the action and indications of the individual hypnotics or the use of hypnotics in a given disease.

M. Huchard thought that there were two points to be considered in a discussion on hypnotics: 1. The physiological question, which had been treated brilliantly by M. Bardet, 2, The question of hypnotic medication, as M. Paul had suggested. Hypnotic medication might be carried out with a hypnotic drug or by counteracting the cause of the sleeplessness; it was in this way that a milk diet overcame the insomnia observed in connection with tonic dyspnæa in certain patients with heart disease, that the bromides put a stop to insomnia of nervous origin, and that codeine acted as a hypnotic by allaying cough. He did not altogether agree with M. Bardet as to chloral and its derivatives, for in persons affected with heart disease manifested by defective systolic energy, chloralose gave excellent results, while chloral was dangerous. In cases of aortic disease, in his opinion, morphine was the drug to be chosen. He called attention to a very interesting little fact which had been noted by Claude Bernard in his experiments on dogs, to the effect that sometimes, after an injection of morphine, a considerably heightened acuity of hearing occurred, so that the least sound might keep the patient from sleeping; he advised, therefore, that perfect silence should be maintained about a person to whom an injection of morphine had just been given.

The Toledo Medical College. - The secretary of the college, Dr. William J. Gillette, has sent us a copy of a letter written to him by the secretary of the Illinois State Board of Health, dated February 1, 1894. The letter is as follows:

"The committee on the administration of the Medical Practice Act submitted their report to the State Board of Health at its recent meeting held January 30th, recommending the recognition of the Toledo Medical College as in good standing before this board for the purpose of the medical practice act. The report was unanimously adopted and it was ordered that the secretary recognize the diplomas of said college as the basisupon which to issue the State certificates entitling to practice medicine and surgery."

Warm Fomentations of Corrosive Sublimate in the Treatment of Erysipelas .- The Journal des praticiens alludes to a recommendation of this method of treating erysipelas, by Labanowski, in the Archives de médecine et de chirurgie militaires, as being preferable to spraying. A compress wet with a 1-to-1,000 solution is to be applied to the affected part every hour. It is said that the pain is allayed almost immediately.

SOME DEFECTS IN ANATOMICAL TEACHING IN THE MEDICAL SCHOOLS OF THE UNITED STATES.\* By JOHN B. ROBERTS, A. M., M. D.

It has been truly said that anatomy and physiology are the foundation upon which the whole structure of medical education is built, and that consequently these sciences must be taught with exhaustive thoroughness and made the permanent intellectual property of the student.

The best medical schools in this country, with their four years' graded course requisite for the medical degree, have now attained an excellence probably not inferior to any similar educational institutions in the world. There still exist here, however, numerous useless and low-grade medical schools, destined to be soon destroyed by the rapidly increasing number of State medical examining boards. In some of the former class of schools, and in nearly all of other grades, anatomical teaching has not reached the standard which the essential character of the subject demands. A consideration of the causes of this defective instruction and a search for efficient remedies seem appropriate. It is my hope that you who are present will discuss the statements of this address freely and fully, so that each of us may thereby find suggestions of value in elevating and improving the work done in our own schools and States.

It is a notorious fact that few of our students have any knowledge of biology when they begin the study of human anatomy. I know of but three schools in the United States (Johns Hopkins University, University of Michigan, and Hahnemann Medical College of Philadelphia) where a preliminary examination in elementary biology is required. Although an entrance examination in physics is enforced by many medical schools, there are others which admit without any such requirement. In those which submit students to this preliminary test the examination is probably confined to very elementary questions. Several of our very best schools still allow young men' to begin the medical curriculum without any previous study of Latin. It is a little embarrassing to know that students entering homœopathic colleges are required by the American Institute of Homeopathy to possess a broader general education than is demanded of our students by the American Medical Association, the Association of American Medical Colleges, or our best medical schools. The preliminary educational requirements of the Hahnemann Medical College of Philadelphia include botany, chemistry, biology, physics, and Latin. Certainly not more than one or two of our schools include all of these topics in the entrance examination.

It is not difficult to appreciate the confused ideas of human anatomy obtained by a first-year pupil who knows

little physics, less biology, and no Latin. What wonder that he fails to remember the names of the bones and muscles, and is filled with consternation when asked to mention an instance in the human body of a lever of the third class! He has no conception of the meaning of the descriptive Latin names of anatomical structures; wonders what is meant by "lever" and other mechanical terms; and is at a loss to know the significance of the terms "dorsal," "ventral," and "thoracic," and iter e tertio ad quartum ventriculum. Did not I, as a student, sit next a man who was unable to understand the function of certain laryngeal structures because the professor attributed to them a mysterious use called "phonation"?

Yet under our present system such students listen to lectures on osteology, syndesmology, and myology, and are expected to learn practical anatomy by dissecting the human body. To call such indecent butchery dissection is a farcical misnomer, as every demonstrator of anatomy knows. It would be much better to let these ill-trained hands learn the difference between muscle and fascia, nerve and vessel—which is about all such bungling teaches them —upon the dead bodies of the lower animals, and postpone dissection of human cadavers until the second or third year of the course.

Ebers has told in fiction of the Egyptian physician who, in the fourteenth century before Christ, ran the risk of condemnation by his heathen gods in order to obtain a human heart for studious dissection. You may remember his chagrin at finding his dearly bought prize so like that of the brutes he had often slaughtered in his quest for knowledge. Let the student of to-day begin his anatomical studies on the body of a dead cât, and he will learn much that will enable him to prosecute investigations in human anatomy with the ease of one to whom its fundamental principles are already known.

One of the most detrimental results of the acceptance of medical students without preliminary education is that they have had no educational training in using their eyes and hands. An hour's stay in any dissecting room will prove this point. Here is a man holding his forceps as if it were a pair of fire tongs-there, another making a fruitless attempt to put an edge on his scalpel. Few students can describe what they see, and still fewer can make the crudest diagram of their findings. In scientifically conducted anatomical laboratories pupils should be required to describe orally or in writing what they uncover, and should make drawings of the more important features. This method is adopted in non-medical schools and in the study of histology and pathology in some medical institutions. It is undoubtedly the true method of educating the mind, which is not a receptacle to be simply filled with statements thrown into it from the lips of teachers. That which enters by the ears may lead to culture; but Nasmyth, the Scotch engineer, spoke truly when he wrote, "The eyes and the fingersthe bare fingers-are the two principal inlets to sound practical instruction." Who doubts that the anatomical discoveries of Ruysch in the early part of the eighteenth century were due to his possessing "the hands of a fairy and the

<sup>\*</sup> The opening address by the executive president of the Section in Anatomy of the First Pan-American Medical Congress, September 5, 1893

eye of a lynx"? A recent writer on education avers that only in Germany and such countries as neglect to educate the young by means of manual training do we find men of learning who can scarcely sharpen a pencil without cutting their fingers. My experience in post-graduate teaching convinces me that for this reason operative surgery is impossible for some very intelligent physicians.

Manual training is valuable, moreover, because, as Felix Adler has said, hand culture brings brain culture. We need not only the worth and beauty of the object made, but also the psychological result brought by the effort for the utilitarian end. Physicians know that Seguin actually created intelligence in the idiotic brain by manual training, and that mental discipline must not be too much subordinated to mechanical accuracy. The medical growth of not a few capable minds has been dwarfed by modern instruments of clinical precision. The time has certainly come when the medical schools of the United States should insist upon a preliminary examination in elementary biology. A soon as this requirement can be extended to include as certain amount of laboratory work in biology, students will have sufficient deftness and manual dexterity, added to their preliminary knowledge of natural history, to fit them for intelligently studying descriptive and practical human

As you probably know, the British five-year medical course is reduced to four years in a medical school, if the registered student has previously been graduated in arts or sciences at a recognized university requiring a year in physics, chemistry, and biology. If no such general education has been obtained, these subjects are studied during the early part of the professional curriculum, which is then of necessity five years in length. In France the preliminary education of one who aspires to become docteur en médecine must show evidence of his having had instruction in natural history, as well as in all topics of general education. Germany and Italy also require a preliminary knowledge of natural history, as probably do all the European nations, except Belgium. In Brazil and, I think, in the other Latin American countries a biological requirement is a necessary part of the preliminary education of those who purpose beginning medical studies.

A young man desirous of entering a medical school had much better wait a year, and devote that time to biology, chemistry, physics, and Latin, than to attempt to begin professional study without an elementary acquaintance with these subjects. The university extension courses will, in many sections of the country, give him the needed opportunity. If no such courses are accessible, a few books, even without a teacher, would answer the purpose.

If it is true that much unsuccessful anatomical teaching is due to the poor quality of the recipients, it is none the less demonstrable that a more extended influence for evil is exerted by the inferior mental qualifications of teachers and the unscientific methods of teaching permitted in some schools. This is, to a certain extent, the result of a custom that permits a professor, once appointed, to hold his position without forcible criticism until he dies or resigns, and prevents the faculty as a body influencing or

regulating the manner or mode of instruction. The occupant of a professorial chair is practically an autocrat by courtesy.

Puschmann says that in the eighteenth century anatomical demonstrations on dissected bodies were frequent in many European universities, but that "in other places the neglect of anatomical demonstration was caused not so much by a scarcity of bodies as by the idleness and ignorance of the professors." Such a statement, it is to be feared, is not altogether inapplicable to the anatomical instruction now given in some quarters of the United States. Some men of great learning can not teach; the faculty of imparting knowledge is distinct from the faculty of acquiring knowledge. To teach is not simply to tell, but to make the fact stated so interesting and so clear that it assumes a living importance and is eagerly sought and intelligently retained by the hearer as a part of himself. A teacher must draw bold, clear outlines, omitting details and repeating essentials until his pupils have a mental framework upon which they themselves may erect more elaborate structures at a future time.

He who has not the power to select the essentials and lead the scholar to reason and observe is destitute of the teaching instinct. Then his lectures become mere recitations, as wearisome to himself as to his involuntary hearers. The true teacher furnishes his pupil with compass and chart; no more. The latter must select his route and reach his harbor by the exercise of those intellectual powers which have been given him. It is experience and not memory that has been called the mother of ideas.

Few teachers of to-day read their lectures on anatomy; but in some cases the lecture is still as lifeless as if read from manuscript or text-book, and destitute of either demonstration or true teaching. Didactic teaching can not be entirely relinquished, but it has little place in anato-Demonstration by specimen, dissected cadaver, blackboard diagram, and living model must be the chief reliance of the professor of anatomy who' desires to hold the attention of his class and make anatomy what it is-one of the most interesting branches in the medical curriculum. Not many students will be absent from the lecture hour devoted to anatomy if they know that the statements read in their text-books are to be verified by electrical stimulation of the muscles on the nude model; that they are to see with their eyes and feel with their hands the difference between artery, vein, and nerve; that the teacher will create in colored crayon on the blackboard the diagram illustrating the relations of bone, muscle, and viscus; that the dissected cadaver will be studied in the standing posture; that the muscles of expression will be illustrated by photographs and etchings of public characters; that surface anatomy will become interesting because studied on reproductions of the famous works of ancient Greek art.

Muscular actions can only be taught effectively by voluntary use of the muscles of nude models, or by their involuntary contraction induced by the electrical current. Bones and other specimens in the hands of the instructors are of little value to the student seated twenty feet away. This distance effectually prohibits the latter from seeing the fissures, grooves, and foramina so learnedly mentioned by the teacher, who is perhaps simply reading for his own enlightenment the lettering printed on the bone. Even gigantic models in the hands of the teacher are less advantageous than duplicate specimens in the hands of the students during the time of instruction. Some teachers fail to appreciate that an elaborate picture, though valuable for reference by one who has known the anatomical region, is of little service to a student. The crudest diagram, made before the latter's eyes, conveys the idea and fixes it in his brain. A piece of chalk and a blackboard are imperatively demanded whenever and wherever anatomy is to be taught. Yet I recall the dissecting room of a well-known medical school which for years had no blackboard, no chalk, and no skeleton within its walls.

Occupants of chairs of anatomy not infrequently look upon their positions as temporary, and long for the occasion when they may be transferred to a department in which they feel more interest. Who does not know professors of anatomy that promptly became professors of surgery or obstetrics when the opportunity arose? One can as little expect such temporary anatomical chairs to be filled with enthusiastic and successful teachers as to find proper teaching of applied medical and surgical anatomy at the hands of physicians whose daily work is literature or life insurance. Again, it is not reasonable to expect those whose early education has been defective to be able to teach the mutual relations of anatomy to biology, mechanics, and psychology. The student needs a wide preliminary education in general knowledge; but the teacher of anatomy is helpless without it.

No criticism is too severe for the system that places first and second course medical students in one class room to hear the same didactic lectures on anatomy. Such a parody of instruction is probably unknown except in medical schools. To compel half of the class to hear what they can not possibly understand, to force the other half to listen to much that they have already learned, is recognized as idiocy by every one except the professional phonograph that each year repeats at a given hour the words which successive classes have received as teaching. Instruction that is not graded so as to lead step by step to higher knowledge is unworthy the name. It is impossible to compute the lost hours, undeveloped intellects, and disasters in medical practice due to this almost distinctively American folly. This undesirable method of teaching has been retained in the department of anatomy longer than in some other departments, because the important new facts to be taught in anatomy have been less numerous and conspicuous; therefore the whole subject can be pretty completely discussed in one session of lectures.

No method of instruction fulfills its mission if it does not develop the habit of independent investigation and work. Pupils need to be taught the manner of instituting and following out original inquiries and the use of the literature of a subject. Few colleges attempt to thus arouse the powers of observation and to sharpen the senses, for the prizes offered in some schools for a record of anomalies found in the dissecting room scarcely deserve consideration

in this connection. Opportunities for original research in human anatomy are now given and such work is encouraged at the Harvard University Medical School, the College of Physicians and Surgeons of New York, and the Medical Department of Clark University at Worcester, Massachusetts. The last institution, however, confers no degrees in medicine and does not partake of the character of a school for undergraduates. Didactic instruction at the hands of teachers who never contribute a single new fact or thought to anatomical or medical literature is not calculated to encourage a spirit of scientific inquiry in students. The demonstrated usefulness to the scientific world of a teacher's original labor is a powerful stimulant to investigation and scientific rivalry among his pupils. The need of such opportunity and example is much felt in our schools.

In certain things we need to return to methods employed in the middle ages, but later overlooked or forgotten. In the beginning of the fifteenth century naked men were used to demonstrate anatomical facts, and it is possible that outline diagrams of the deeper structure were made on the bare skin. Experience with students has abundantly shown me that such "anatomical clinics" meet with great favor. To group in one lecture several nude models representing the effects of disease on anatomical landmarks is most valuable and essential in teaching and sustaining interest in clinical anatomy. "Clinical conferences," in which before his fellows the advanced student points out and demonstrates anatomical relations upon the living subject, develop a habit of thorough investigation of medical and surgical cases. Its subsequent value in diagnosis is easily appreciated.

This form of anatomical teaching is manifestly impossible to an instructor who has no practical knowledge of diseased conditions. The necessity for comparative anatomy, morphology, embryology, and anthropology in a perfectly arranged anatomical curriculum may require a portion of the instruction to be given by a biologist pure and simple; so long, however, as a medical school is to train medical practitioners, the demand for a physician or surgeon to teach medical, surgical, and artistic anatomy will be imperative. The school that provides an enthusiastic biologist for the one purpose and a practicing doctor for the other will best fill the hours devoted to anatomy in the college course.

The lengthening of the medical curriculum in all schools to compel attendance on four college courses would give time for laboratory work in embryology and comparative anatomy. Graduation should then be deferred until the age of twenty-two years, as is now done in one school (the Woman's Medical College of Pennsylvania).

The museums found in medical colleges lose much of their teaching value because the students have limited access to the specimens. Bones and dissected preparations, both wet and dry, of normal anatomy should be put into the student's hands for comparison with his own dissections and the text-book illustrations. In most cases the teacher alone handles the museum specimens. Wet preparations demonstrating normal regional anatomy are almost unknown in our college collections.

The work done by students in the anatomical rooms would be of a much higher grade if each member of the class was required to draw, even in crude outlines, the structures uncovered by his dissections, and under the guidance of an instructor to demonstrate his findings to his fellows. The necessity of preserving cadavers in this country by vascular injection with zinc chloride and similar decolorizing agents militates to a certain degree against fine work in our dissecting rooms. The adoption of the principle of cold storage by some schools (Bellevue Hospital Medical College, Chicago Medical College, Medical Department of Western Reserve University, and perhaps others) shows a way out of this dilemma.

Examinations in anatomy, which might be public, should be conducted at various periods of the course. Those in the early part ought to be restricted to osteology and similar elementary topics; but the later and more difficult examinations in regional, surgical, and artistic anatomy should be so conducted as to require the use of the earlier knowledge, and include demonstrations of surface anatomy and of dissections. A substitution of English terms for the Latin nomenclature still largely retained in anatomy would aid the average medical pupil to understand anatomical mechanics and remember the facts which he has presented to him. Much was gained in European schools when the mediæval practice of teaching medicine in debased Latin was relinquished. The professor who had to use the vernacular was compelled to be accurate in statement and clear in expression, and could no longer hide his ignorance in high-sounding Latin sentences imperfectly understood by his class.

The true solution of the educational problem in medicine is the discontinuance of the isolation existing between medical schools and schools whose object is general education and culture. Every medical college should be an integral part of a college or university, and should not be managed by men separated from the wholesome educational atmosphere which surrounds institutions devoted to learning in its broadest sense. The perpetuation and organization of isolated medical schools has been the cause of manifold defects in medical teaching, and has ended in making medical pedagogics an undeveloped science. The educational and educative friendships, even the hostilities, engendered by a combination of medical and academical schools, would bring about better preliminary qualifications in medical students and more advanced methods of teaching in professors. It is the school and the man in the corner, who never comes in contact with his superiors, that fails to improve his methods of work. The valuable courses preparatory to medicine now found in several universities would then become more numerous; and more youths, looking forward to a medical career, would begin their studies in such courses if the university and the medical college were everywhere combined. Thus the study of medicine would be a gradual development of the mind, and not a mere attempt to crowd technical facts in the memory -a process in violation of the first principles of education and one which makes many medical journeymen, but few medical masters.

Universities, academies, and all literary schools would be benefited by the association with medical colleges, for it would lead to even greater modification of the formerly rigid classical course by the development of the departments of natural science and languages. This change would meet with the approval of many thinkers, among others the Emperor of Germany, who has in recent years shown the value of youthful energy by insisting upon the necessity of modifying the strict and unyielding classical curriculum so long enforced by the German universities.

# LECTURES ON THE DIAGNOSIS OF ABDOMINAL TUMORS.

By WILLIAM OSLER, M.D., PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

LECTURE II.—NODULAR AND MASSIVE TUMORS OF THE STOMACH.

(Concluded from page 198.)

(b) Tumors of the Body of the Stomach.—Tumors: of the pyloric region often encroach extensively on the anterior wall of the stomach, but I have placed in this category three cases in which the tumor mass appeared to be more in the central part of the organ. In Case XIX the left epigastric region was occupied by a rounded, irregular tumor, and the patient had had marked gastric symptoms and had vomited blood. Though there was no question as to the nature of the growth, it is interesting to note that during his stay in hospital he gained six pounds in weight. In Case XX the tumor mass was more extensive and seemed to involve a large section of the anterior wall of the stomach, forming a very prominent and readily palpable tumor. In Case XXI a large nodular mass could be felt between the left costal margin and the navel. It was unusually firm, and post mortem showed that it occupied more than ten centimetres of the anterior wall of the stomach.

CASE XIX. Large Tumor of the Body of the Stomach.—Gustave P., a shoemaker, aged fifty-three years, admitted December 28, 1892, complaining of pain in the abdomen and back.

Parents died over eighty years of age; one sister died of cancer of the womb.

Patient was born in Germany; has been very healthy; has not been a heavy drinker; and denies lues.

The present illness he dates as far back as eight years ago, at which time he had dyspeptic symptoms, which persisted for two or three years; then he remained quite free from them for about three years, but early in 1890 they recurred. He has had uneasy sensations after meals, and belching, sometimes bringing up acid fluid. During the past summer he had a good deal of vomiting, and once in June brought up dark-brown fluid, which was said to be blood, and the next day the same material was noticed in the stools. His appetite is fair, but he is afraid to eat, and lately has only been taking liquids. He has not lost very much in weight—only about five pounds in the last six months.

Present Condition.—Patient is emaciated, pale, and a little sallow; mucous membranes distinctly anæmic. Tongue has a patchy coating and indented edges. Examination of the thoracic organs is negative.

The abdomen is symmetrical, a little depressed below the costal border; no peristalsis visible. On palpation, the left epigastric region is occupied by a superficial mass with a rounded,

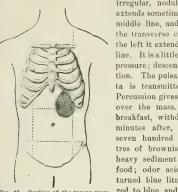

Fig. 16.—Outline of the tumor mass in Case XIX.

irregular, nodular surface. It extends sometimes almost to the middle line, and below crosses the transverse costal line. To the left it extends to the nipple line. It is a little painful on firm pressure: descends with inspiration. The pulsation of the aorta is transmitted through it. Percussion gives a flat tympany over the mass. Ewald's test breakfast, withdrawn fifty-five minutes after, yielded about seven hundred cubic centimetres of brownish fluid with a heavy sediment of undigested food; odor acid. The filtrate turned blue litmus red, congo red to blue, and yielded a rosered color with phloroglucin vanillin. Uffelman's test nega-

tive. The urine was normal. The patient remained up and about the ward, and with a careful diet was made much more comfortable. The condition of the gastric juice was frequently tested; thus on January 4th Ewald's test breakfast, withdrawn an hour later, yielded about five hundred cubic centimetres of sour, yellowish food matter, which gave the reactions previously noted.

The patient continued to improve, gained in weight from a hundred and fourteen to a hundred and twenty pounds, and was in every way more comfortable. He had almost constantly, while in hospital, a little fever, temperature rising to 100°, sometimes to 101°, every day. No special change occurred in the position or condition of the tumor mass. He was discharged February 27th, and has not since been heard from.

Case XX. Tumor of the Body of the Stomach.—N. R., aged

Fig. 17.—Area of the tumor mass in

sixty-nine, shoemaker, German, came to this country in 1872. Admitted March 13th, complaining of loss of appetite, nausea, and vomiting.

Patient was sickly as a child. Six years ago he had a fever which kept him in bed for three weeks. He had been a moderate drinker; denies syphilis. Has not been a dyspeptic.

Present illness began before Christmas with pain after eating, nausea, and vomiting, the latter usually a short time after taking food. The appetite has failed and he has lost rapidly in weight. He has had much fullness and distress in the epigastric region, but no very sharp pain. Of late all these symp-

toms have become aggravated. He has never had vomiting of large quantities of food.

Present Condition.—Patient is a large man, still fairly well nourished. The lips and nuccous membranes are pale; tongue has a thick white coat. Pulse is regular, 64, tension slightly increased the vessel wall sclerosed. Tempera-

ture is normal. Examination of the thoracic organs is negative.

The abdomen is symmetrical, except that there is a slight prominence at the end of the tenth rib on the left side; on palpation, soft, and nothing is felt until the epigastric region is reached. In the region indicated in the figure is a mass which moves freely in inspiration. The lower border is sharp like that of the liver or spleen; the surface is irregular and somewhat nodular. On percussion, there is a distinct tympany over the mass. On inflation, at there is no abnormal dilatation of the stomach.

Ewald's test breakfast given at 8 a.m.; at 9.30 a tube was inserted. There seemed to be some slight obstruction about the cardiac orifice, and about fifty cubic centimetres of coffee-colored fluid removed, together with a very little fresh blood. There was no free hydrochloric acid. Microscopically, it presented fresh blood-cells, blood pigment, and remnants of food. No enlargement of the lymph glands.

No material change took place within two weeks in the patient's condition; he was evidently failing, and he decided to go home.

Case XXI. Tumor of the Pyloric Region and Anterior Wall; Perforation; Peritonitis.—August B., aged fifty-eight years, farm laborer, German, admitted complaining of pain in the abdomen, loss of appetite, vomiting, and insomnia. Father died aged fifty-six, cause unknown; mother, of dropsy at sixty; one sister died of cancer of the stomach; no history of tuberculosis in the family.

Has always been a healthy man; the father of seven children. Has been a moderate drinker; denies venereal disease. Has always had good digestion; never suffered from dyspepsia.

His present illness began four weeks ago with pain in the abdomen and vomiting, which comes on very shortly after eating. He has never vomited any great quantities. Though he does not appear to have had any marked stomach symptoms, during the past six months he has lost in weight from a hundred and sixty-five to a hundred and thirty-five pounds. Patient is a medium-sized man, pale, thin, lips and mucous membranes pale, and he looks somewhat cachectic. Thorax is symmetrical; above the left clavicle one of the lymph glands is enlarged and hard. Examination of the lungs and heart negative.

The abdomen is full, particularly in the right epigastric region. Here, on palpotion, a nodular mass can be felt midway between the costal margin and the navel. It is flat and extends transversely as far as two cubic centimetres beyond the median line. It is hard, a little painful, and descends with each inspiration. It is resonant on percussion. No peristalsis was felt, no changes in consistence, and no gas was felt to pass. The stomach tympany begins at the seventh rib in the left parasternal line and does not quite reach the navel. After inflation of the organ no peristalsis is seen.

Test breakfast was given and a tube inserted an hour afterward. The fluid obtained was dark-brownish, with a sour odor; contained organic acids, but no free hydrochloric. The blood count showed hemoglobin forty-five per cent., and the red blood-corpuscles about four million.

The patient left the hospital and was readmitted April 12th, and the following notes were made: He is very emaciated and looks cachectic. There is a marked prominence in the epigastric region, just below the ensiform cartilage, and here very slight irregular movements may be seen. The indurated mass noted above appears to have increased in size. It lies at the junction of the umbilical and epigastric regions, and, on inspiration, descends almost to the navel. It is firm and resistant. There is no peristalsis visible after inflation of the stomach, and no

change in the position of the tumor. Just above the navel in the linea alba there is to be seen a flattened prominence, which feels soft and like a little fatty tumor beneath the skin. Patient became progressively weaker and died June 4th.

Autopsy.-Peritoneal cavity contains nine hundred cubic centimetres of turbid fluid; fibrinous exudate covers the intestines. There is a large tumor mass to the left of the pylorus, involving the anterior wall of the stomach nearly to the cardiac end. Midway between the greater and lesser curves is an oval perforation, measuring seven by three millimetres, through which the contents of the stomach can be squeezed. On opening the stomach, there is a large ulcerated cancer extending laterally for ten centimetres. The stomach walls in the neighborhood of the ulcer are much infiltrated and are raised and in places overhang the ulcer. In the anterior wall there is the perforation already mentioned. The ulcer does not extend to the pyloric ring. The glands about the stomach and pancreas are enlarged. The head of the pancreas is also involved. There are small white tumor nodules on the surface of the omentum and mesentery.

Death from perforative peritonitis is a not very uncommon complication of cancer. Perforation may also take place externally. A more common communication is with the colon, which in all probability took place in Case XXIV. A rare perforation in cancer, which I do not see mentioned even in the exhaustive article of Professor Welch, is into the pericardium, which I found at autopsy in a case of the late Palmer Howard's, of Montreal. There was, of course, the most intense pericarditis, and the group of physical signs of pneumopericardium.

(c) Massive Tumors of the Stomach.-No cases are more difficult to recognize than those in which the walls of the stomach are extensively infiltrated. You might think that under these circumstances the diagnosis would be made with the greatest ease, but in reality they are cases which require no little care and study. Of the three cases which I shall narrate to you, in one the diagnosis was easy and definite; in one the tumor was so extensive, occupying such a large area in the left side of the abdomen, that some doubt existed as to whether it was not associated with the spleen or the kidney, while in the third there remains a doubt as to the exact nature of the growth.

Case XXII. Cancer of the Stomach; Prominent Tumor in the Epigastric Region .- H. P. C., aged fifty-seven years, admitted September 1, 1892, complaining of loss of appetite, progressive weakness, and irregular pains in the abdomen. Family history is good; parents lived to old age.

Patient since childhood has been healthy; appetite always good until about six years ago, when he began to have dyspepsia, occasional attacks of nausea and eructations, and sometimes vomiting. He appears at this time to have had considerable gastro-intestinal disturbance, as he had also diarrhea, and became very weak and emaciated-quite as much so, he says, as he is at present-and the ankles were also swollen. The vomiting and nausea and diarrhoa stopped and he gained in weight, but his digestion for the past five years has not been as strong as before the illness six years ago. In June of this year he began to have feelings of oppression in the stomach, as though he had eaten a very full meal, but he had no vomiting; once or twice the food has been regurgitated. A marked symptom at first was inability to swallow after the second or third mouthful. With these local symptoms there has been loss of appetite

and progressive emaciation. He has lost forty pounds since June. He has never had any severe pain; only a feeling of heaviness and distention after eating.

Condition on Admission .- Patient is a large, well-built man; face pale, and he looks depressed. There is marked emaciation. The pulse is of fair volume and the heart's action is strong. The temperature during the sixteen days he was under observation was always a little elevated toward evening, rising on several occasions to 102°. He had no cough; respirations quiet.

Abdomen flat, except in the epigastrio region, in which it is a little prominent. On palpation, it is soft, painless, and just below the ensiform cartilage, extending across the whole upper zone, is a firm, resistant mass. Above, it extends to within two inches of the ensiform cartilage, and the lower margin was rather more than this distance from the navel. To the left it passed under the costal margin opposite the seventh and eighth cartilages. To the right it reached nearly, but not quite, to the costal margin. There was a distinct concavity above and a convexity below, and at no time was the mass below the level of a line joining the tips of the eleventh ribs. It was at times much more prominent than at others. On palpation, it was firm, gave an impression of solidity, was quite painless, of uniform

resistance in all parts, and toward the left passed beneath the costal margin. To the right it terminated at a much higher position than is usual for the pyloric orifice. No movements were noticed in it, but the hand placed upon it occasionally felt distinct gurgling. Everywhere over it there was, on percussion, modified resonance. There were no nodules.

At no time during the patient's stay in the hospital was there vomiting, nor could it be said there was marked distaste for food. At first he took an ordinary diet, but, finding that it gave a good deal of distress, it was replaced by a liquid diet of egg albumin and milk, which agreed very well. Mentally he was very despondent.

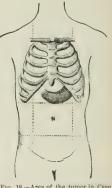

Fig. 18 .- Area of the tumor in Case XXII.

Bismuth and soda were at first given an hour or so after eating, and they relieved promptly the sense of oppression. It was not thought worth while to distress him with attempts at lavage or test breakfasts. Patient left the hospital unimproved on the 19th.

Patient died September 28, 1892.

Case XXIII .- Unusually Large Cancer of the Stomach .-Mrs. L., aged about fifty years, seen September 12, 1892. The patient has been a high strung, nervous woman, and has not been in her usual health for the past two years, complaining chiefly of weakness and ill-defined nervous symptoms. I saw her a year ago for these symptoms, and at that time made an examination of the abdomen, which was negative. In June she was seen by a physician, who tells me that there was a lump on the left side which he thought was a floating kidney.

During the early summer she was under the care of a New York quack, who put her upon meat diet and hot water, under which treatment she appeared to improve. She went north to a watering place, and, though growing weaker and losing rapidly in weight, she kept up until August, when, on account of the swelling of the feet, she consented to go to bed. All this time she was chiefly on the meat diet, and apparently digested it very well, as she had no eructations and no vomiting. Subsequently she had a more varied diet and complained a good deal of distention and uneasiness after eating, and on several occasions had regurgitation of food. The lump in the left side had apparently increased in size, but caused her very little pain, except when it was rubbed by the masseuse.

The condition when I saw her was as follows: Profound emaciation, particularly marked in the face. The mind quite clear; the voice strong, and the grasp of the hand firm and good. In spite of great wasting, she did not look cachectic, and the color of the lips was good. Pulse 84, of fair volume; temperature normal. Tongue was red with a light furry coat. Her chief complaint was of uneasy feelings of distention after food, and of the weakness and prostration. The sleep was not, as a rule, disturbed, though she had been taking opium suppositories to allay the irregular pains in the side. She had no cough; no diarrhæa.

The abdomen was a little distended, contrasting with the extreme emaciation of the thorax. The upper zone was full and the skin over the left hypochondriac and umbilical regions reddened with applications, and these parts looked the most prominent. No peristaltic movements were noticed on inspection. On palpation, there was felt a large mass occupying the area shown in the annexed diagram, extending to the right 2.5 centimetres beyond the navel and the same distance below. The edge passed transversely to the left to a point four centimetres

Fig. 19. The tumor area in Case XXIII.

above the anterior superior spine; the edge could then be followed readily in the line of this spine to the point of the last rib. Above, it passed beneath the costal margin, and the upper line reached to within five centimetres of the ensiform cartilage. It felt superficial, firm, not tender; below and to the right the edge was unusually distinct, and just at the navel there was a slight depression. The hinder edge could be distinetly felt, and it did not pass deep into the renal region.

On bimanual palpation, the mass could be moved slightly. At the first examination there was no gurgling to be felt. On percussion, it was flat in the

greater portion of its extent, but in the right fourth of the mass it was distinctly resonant.

There were no glandular enlargements. The blood examination was negative, with the exception of a very great increase in the blood plates.

I was not a little puzzled at first as to the nature of this tumor. The situation, the flatness, its superficial character, excluded definitely, it seemed, a movable kidney, which would not for a moment have been considered had I not been informed that a physician in whose judgment I have great confidence had in June pronounced this to be the condition present. The situation was suggestive, naturally, of an enlarged spleen; the right edge seemed thin and there was an indistinct feeling of a notch, but the very superficial character, the absence of a definite notch or notches, and, above all, the resonance over one half of the tumor, seemed inconsistent with this view. A phantom tumor in a hysterical woman had also been suggested. The large size, the unusual situation, and the slight

character of the gastric symptoms did not favor gastric carcinoma, suggested, of course, by the profound emaciation and the existence of a resonant tumor in the left hypochondrium.

The next few days, however, developed additional symptoms which made this view very much more likely. On the 12th she had taken six oysters and one on the 13th. On the 15th she had eructations of dark, very offensive material, and regurgitated one of the oysters in a condition of decomposition, but undigested. On the 16th she regurgitated the chopped meat in a similar condition of decomposition, and a second oyster which had been very slightly acted upon. The odor of the materials brought up was intensely offensive. She had also at this time slight diarrhæa. The tumor did not show any material changes, but the area of resonance seemed to vary somewhat, and, on drinking, gurgling could be distinctly heard over the mass, and sometimes with the hand upon the tumor the flatus could be felt.

September 19th.—For the first time the patient to-day had attacks of actual vomiting, the first at about six in the morning and the second at noon. On both occasions she brought up about half a pint of dark, bloody fluid of a most horribly offensive character, having a distinctly fæcal odor, as well as an odor of decomposition. In the material last vomited there were several grayish, sloughy masses the size of peas, which under the microscope did not show any definite structure. The patient after these attacks was much exhausted.

For a week after this there was vomiting and at intervals entire inability to take food, and occasionally vomiting of the same offensive material.

Died gradually of asthenia. There was no autopsy.

The extent of the tumor was due to infiltration of a very large area of the anterior wall and fundus of the organ. In all probability there was also extension to the omentum and to the colon. Evidently sloughing took place in the tumor mass, and, judging from the fæcal odor of the vomitus, perforation into the colon had occurred.

Case XXIV. Large, Massive Tumor in the Epigastric and Upper Umbilical Regions.—Patrick C., harness maker, aged fifty-six years, admitted April 15th, complaining of weakness and a lump in the left side.

Family history is negative; father died of accident; mother, cause unknown, aged fifty-five years.

Patient has never been a very strong man; was hurt when a lad by falling off a load of hay; rheumatism in 1876. Has always been rather pale; lived a sedentary life; has not been a heavy drinker; never had veneral disease. Within the past year he has lost between twenty and thirty pounds in weight.

Present illness began about a year ago with diarrhoa, which persisted for between eight and nine months. Sometimes he would have four or five stools in an hour, and often as many as twenty in a day. Never passed any blood; sometimes would have none for two days. Was always better when he rested in bed. Thirteen weeks ago he left off work on account of the weakness, and during this time he has been rather inclined to constipation. He thinks he has become paler. One day about three months ago he felt a lump under the left ribs, and this, he thinks has increased in size. His appetite has been variable; lately it has improved somewhat. He has had no nausea and no vomiting; no trouble in digesting his food. Once or twice has had slight nausea after taking milk. Has had no pain; only a slight heavy feeling in the left side.

Present Condition.—Patient is pale, but not specially emaciated; hair and beard gray; conjunctive pearly white. Tongue lightly furred. Pulse, 96; vessel wall not sclerosed.

Abdomen a little prominent to left of navel; throbbing of abdominal aorta marked. Subcutaneous veins not enlarged. On palpation, occupying the left hypochondriac, the left half of the epigastric, and the upper and left part of the umbilical regions, is a large flat mass. To the right it extends a little beyond the navel, and here the edge can be felt, and at the lower part the suspicion of a notch. The upper limit is ill-defined. At the costal margin it is felt to extend a short distance under the ribs. On deep inspiration the hand can be placed between the costal border and the tumor, which in this region has a distinctly rounded globular surface. Above and to the right it can be separated distinctly from the liver. During inspiration and on deep palpation no splenic margin can be detected in the normal position. On prolonged palpation of the tumor, no changes in consistence can be felt; no gas is noticed to bubble through it.

Percussion.—In the middle line there is no dullness. There is resonance over the whole tumor. A modified, flat tympany is elicited in the left half of the epigastric region. The stomach tympany begins in the parasternal line at the upper margin of the seventh, and extends to two fingers' breadth above the navel. The artificial inflation of the stomach did not show any marked changes, and no gas was felt bubbling in the mass. The distention of colon with air made no change in it.

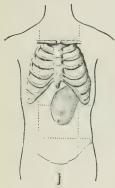

Fig. 20.—Outline of the tumor in Case XXIV.

The mass is distinctly, though not very freely, movable. It can not be pushed back under the costal margin, and in fact can not be moved to the left so that its right margin is beyond the middle line. It does not extend deep into the renal region, palpation in which is normal. The tumor mass is not at all sensitive. The liver dullness is reduced; in the nipple line not more than a finger's breadth; in the axillary line no actual dullness. Though there is this extreme diminution in the area of liver dullness, the edge of the organ can be distinctly felt just below the costal margin. Although the edge of the spleen could not be felt under the left

costal margin, there was at the first examination definite splenic dullness over the ninth and tenth ribs in the mid-axillary line. The blood condition shows a profound secondary anamia and is not specially suggestive of a splenic form. The examination shows only thirty per cent. of hæmoglobin, a little over three million red blood-corpuscles to the cubic millimetre, and a little over nine thousand white corpuscles.

The urine is negative, pale, no abnormal deposits, no casts. He is constipated. Stools formed, and presented no special features.

A test breakfast showed no free hydrochloric acid.

Comments.—April 19, 1893. It has been suggested that this mass might possibly be a dislocated and fixed spleen, but the solidity and firmness, the rounded character of the mass, and the indefiniteness of the notches (supposed to be felt) were against this. Moreover, dislocated enlarged spleens are usually very mobile, and, most important of all, the splenic dullness was quite marked in the mid-axillary line, and the mass was everywhere resonant.

One of the most suggestive features of the case is the onset of the disease with diarrhoa. The situation of the mass, its

fixity, and its size are against tumor of the colon. There are, on the other hand, instances of malignant disease of the small bowel in which the tumor mass has attained a very large size, and in which progressive emaciation, anemia, and diarrhea have been the main symptoms. The most remarkable case of this which I call to mind is one which I saw at the General Hospital, Montreal, with Dr. Molson, for whom I made the dissection. A man, aged forty-one years, was admitted on March 4, 1882, with swelling of the feet, vomiting, and constipation. For six months he had had pains and vomiting and more or less constipation, with loss of flesh. The patient had general anasarca and shortness of breath. The abdomen was full and large, and the examination was very difficult on account of the infiltration of the abdominal walls, and there was ascites.

The post-mortem showed a large mass occupying the left half of the abdomen, from the ribs to the crest of the ilium. It was firmly attached to the left kidney behind, and the colon and sigmoid flexure were at its left border. It was removed with the small intestine, and the tumor was found to involve eighteen inches of the jejunum, which tunneled the mass in a curved direction. The walls were in places from six to eight inches in thickness. The lumen was expanded, the mucosa still evident, presenting blunt valvulæ conniventes.

In Case XXIV the main portion of this tumor is in the epigastric region in the situation of the stomach. Though firm and solid, it was resonant, and, in the absence of definite features, the probabilities seemed to me that it was a large, massive tumor of the anterior wall and fundus. He died in October, with what symptoms we could not learn. There was no autopsy.

Finally, let me sum up a few leading points for your guidance, based on the study of the cases we have had under consideration:

- 1. Though only a small section of stomach is available for palpation, a very large proportion of all tumors of the organ may be felt, owing in part to their greater frequency at the pyloric portion, and in part owing to the frequent depression of the organ. In every one of the twenty-four cases a tumor or induration was detected, and it is interesting to note that in the same period of time during which these cases were observed no instance came to autopsy with a tumor at the cardia or posterior wall.
- 2. In a considerable number of cases the dilated stomach itself forms a tumor in the abdomen, characterized by undulatory peristalsis, sometimes by a definite stomach contour. In ten cases of the series these features were distinct enough to render the diagnosis clear on inspection alone.
- 3. In a majority of cases no serious trouble is experienced in determining whether or not a tumor is in the stomach. Excessive mobility of a pyloric growth and extensive infiltrating masses in the epigastric region were the only conditions causing trouble in any of the cases of this series. The more systematic and thorough the examination, the less is the liability to error.
- 4. The character of the tumor is rarely in doubt. Large, nodular, and massive growths are invariably cancerous. At the pylorus it may be difficult to distinguish between cicatricial thickening about an ulcer, hypertrophic stenosis, and annular scirrhus. It may, in fact, be impossible to decide the question. The age, previous history, the general and local conditions—all have to be carefully taken into account, but, as in Cases XIII, XIV, and XV, it may not be possible to reach a definite conclusion.

And, lastly, the very serious nature of tumors of the stomach may be gathered from the fact that, of the twentyfour patients, eight have already died.

## A PECULIAR CHROMATOGENIC BACILLUS.

BY LOUIS C. AGER, M. D.,

ASSISTANT BACTERIOLOGIST TO THE HOAGLAND LABORATORY, BROOKLYN.

Although chromatogenic saprophytes are too numerous to be worthy of a great deal of attention, the peculiarity of chromogenesis in the case of the following bacillus seems noteworthy. It is quite probable that many of the common organisms, if grown on suitable media or in the presence of suitable chemicals, will develop chromatogenic power as does this bacillus. Investigation along this line of biochemistry may show some interesting facts, and may yield results very useful in bacteriological diagnosis. A little work of this kind has been done by Wurtz in the differentiation of Bacillus coli communis and Bacillus typhosus.

I found the organism here described, and for which I would suggest the name Bacillus violaceus sacchari, in a contaminated tube of glucose-agar, while I was stationed at the United States Army bacteriological laboratory at the Chicago Exposition. The growth attracted my attention on account of the vividness of its color, and I inoculated a tube of ordinary agar, which, to my surprise, showed only a creamy white growth. A further study of the organism gave the following results.

Morphology.—On solid media, a small oval bacillus very like a micrococcus, with a few longer rods. In bouillon and in liquefied gelatin the elements are somewhat longer and sometimes they assume a comma form of about two thirds the size of the cholera spirillum.

Biological Characteristics.—A strictly aerobic, liquefying, chromatogenic (on sugar-agar), non-motile bacillus. Spore formation not observed. Grows rapidly at room temperature. In gelatin roll tubes minute spherical colonies develop at the end of two days. They are white, translucent, homogeneous, liquefying the gelatin very slowly, and never attaining any great size.

In sugar-agar plates the colonies are characteristic. The deep colonies are lenticular and opaque with clearly defined edges. The superficial colonies are white, translucent, and slightly granular, round, or somewhat oval, with clearly defined edges. They have usually a lenticular-shaped nucleus, showing their development from deep colonies. When viewed from the lower side they show four distinct zones—the opaque lenticular nucleus, a dark purple homogeneous area, then a narrow ring of deep red, and beyond that a translucent white zone.

This organism grows rapidly on agar, on glycerin-agar, and on potato, forming a thick, creamy white coat in concentric rings without pigment. It liquefies gelatin slowly, be-

ginning on the third or fourth day, more quickly if grown in the dark. In litmus milk it has an acid reaction and a peptonizing effect.

Chromatogenesis.—This organism produces no pigment except in sugar-agar. In that medium there is at first a creamy white growth, but at the end of two days the agar begins to assume a blue tinge which deepens gradually to a brilliant purple near the surface, shading to a dusky red in the depth of the agar. No color is produced if the organism is grown in the dark. The pigment is soluble in water, insoluble in alcohol. At the end of two or three weeks the color begins to fade, changing at the end of a month to a dusky red.

Pathogenesis.—A small quantity of this organism inoculated into the ear vein of a rabbit gave no result.

# THE PRACTICAL MANAGEMENT OF STRICTURES OF THE URETHRA.\*

BY CARTER S. COLE, M. D.

To bring before this society a subject so familiar, particularly in view of the experience at Charity Hospital, might to many seem to be a work of supererogation; and yet it is hardly probable that no one else but myself found that in the management of cases in private practice the methods of treatment with which we were familiar were not always satisfactory or applicable, or else a definite plan of treatment from the time the patient presented himself until the time he ought to be practically well was not an easy matter to formulate.

The explanation of such a condition of affairs has seemed to me to lie in the fact that we were taught to consider only one method of treatment applicable to a great majority of cases, or we were not sure when to vary from any one method or what course to pursue, even though the conditions might be absolutely dissimilar from those with which we were familiar. Back of all this may have lain an indefinite knowledge of the pathology of the condition, or, at least, an uncertain state of mind as to the possible kind of stricture with which we were confronted. To clear up this whole field would, even if possible, take much more time than is at my disposal; but if a succinct review of the pathology of stricture, and on it a working classification, can be given, and if from these some practical deductions can be made as to the management of these cases, it is to be hoped that your time has not been needlessly occupied in the consideration of this subject. From an anatomical standpoint we have the tripartite division into the spongy, the membranous, and the prostatic urethra. It is not a part of our task to review in detail the meatus with its fossa navicularis and lacuna magna, the anterior expansion and the posterior, bulbous expansion of the first named (and in this latter the openings of the ducts of Cowper's glands), the whole about six inches; nor of the second to more than recall that it measures three quarters of an inch

<sup>\*</sup> Read before the Society of the Alumni of Charity Hospital, No vember 1, 1893.

on the roof and half an inch on the floor of the canal, and extends from the anterior base of the triangular ligament to the apex of the prostate; nor of the prostatic urethra, in which stricture does not occur, to do more than remind you of the importance of the various structures opening upon its floor (the veru montanum with twenty or thirty ducts of prostatic follicles on either side, and in front the sinus pocularis or uterinus masculinus, upon whose margins the ejaculatory ducts open). The glands of Littre, with their sinuses (Morgagni) directed and opening toward the meatus, are of some clinical importance. Histologically, the mucous, muscular, and erectile coats comprise the urethra, the former consisting, excepting the pavement epithelium immediately behind the meatus, of columnar epithelium, with little areolar tissue beneath; the muscular, of longitudinal and circular fibers interspersed with fibroelastic and fibro-connective tissue; and the erectile coat of still less fibrous tissue.\*

"The pathological condition varies from an induration and thickening of the mucous membrane, with connective-tissue proliferation recurring in its depth, to the formation of a dense fibrous mass of cicatricial tissue occupying the submucous region and extending into the meshes of the corpus spongiosum." + Keyes thus states the pathology: "The morbid change in organic stricture may be a mere thickening of the mucous membrane, the surface having lost its polish, being congested and perhaps covered with granulations. These changes are the result of chronic inflammation and resemble those which occur in any tegumentary structure of the body which is kept in a condition of mild chronic inflammation-namely, there is a proliferation of cellular connective-tissue elements, and a consequent proportionate increase in the thickness, denseness, and elasticity of the membrane. This process takes place just within and beneath the mucous membrane and not on its free surface, as shown by A. Guerier, who states that in one hundred autopsies of patients with gonorrhea, more than half of whom had stricture, he found the morbid process in these latter always to have acted immediately beneath the mucous membrane and in the spongy tissue. If the stricture is a little more extensive, a few whitish transverse fibers will be found encircling the canal beneath the mucous membrane. If more advanced still, the meshes of spongy tissue will be found glued together, obliterated, and a mass of dense, fibrous, callous material encircling the canal and holding it permanently contracted. Flaps, valves and free bands, adhesions, etc., are formed by atrophy of follicles or of portions of submucous tissue." In chronic granular urethritis Harrison | sums up the changes thus: "To prevent urine soaking further into the tissue, inflammatory exudation is excited, and barriers of lymph, which ultimately become organized, are thrown out opposite the

By Otis, Lydston, and others special stress is laid upon the train of pathological changes consequent upon a loss of elasticity, this loss of elasticity and diminished distensibility being the most potent factor in converting the previous natural and congenital constrictions with comparatively diminished capacity for distention into pathological states demanding operative interference. To this is due the thinning of the mucous membrane and dilatation behind the plastic deposits, and later the infiltration of tissues and the pathological changes consonant with such states.

The ætiology is not a part of our theme, unless to mention that in order to arrive at any classification we must have a "fundamentum divisionis," and none other seems so well adapted to giving us a dichotomous division, and to aid us in the subdivisions. If we allow for our purpose that a stricture of the urethra is such a diminution of its caliber at one or more points as to produce pathological conditions or changes at the site of such diminution or elsewhere, we will have as our division:

A. Congenital.

B. Acquired Traumatic. Infectious.

An acquired stricture may have originated in traumatism and been intensified by infection, or the reverse, and the cause may act from within or from without, or both ways.

Our subdivisions are easily made upon the extent and character of the pathological process; thus we would have soft, cicatricial, and inodular strictures (Keyes); linear and circular, as the deposit lies; single or multiple, as the names imply; of large or small caliber, according to size, etc.

Clinically, whether the cause be traumatism or infection, or both, or whether, following such causes, the loss of elasticity at the seat of the so-called natural constrictions makes it important to treat the latter, we have for practical purposes—leaving, for the present, out of consideration contractions at or within an inch of the meatus—the resilient, the pliable, and the tough strictures, terms sufficiently distinct to indicate the characteristics of the conditions present, and at the same time terms that easily suggest the method or methods we have found useful in their relief. We may for a minute digress to expand the ideas involved in the terminology favored:

- 1. The resilient strictures, as their name implies, easily demonstrate themselves to be such in the examination with a bulb (or urethrometer), yielding easily though giving a distinct grasp as the bulb reaches them, recontracting readily after the bulb has passed.
- 2. The pliable strictures do not give us that sensation of resiliency, are harder to pass with a bulb (or sound), and give us the sensation of an exudative process, in which

places where leakages take place. Thus, splints of plastic tissue are found corresponding with the spot or spots where the epithelium has been so damaged by persisting inflammation as to cease to discharge its normal function. In this strengthening of the urethra we recognize, in the first instance, a conservative action; eventually, however, as in other compensating processes, certain inconveniences follow which constitute, as it were, an independent disease."

<sup>\*</sup> For fuller details consult Gray's Anatomy, also Stricture of the Urethra, by G. Frank Lydston, M. D., 1893.

<sup>†</sup> Morrow. A System of Genito-urinary Diseases, Syphilology, and Dermatology, p. 268.

<sup>‡</sup> E. L. Keyes. Genito-urinary Diseases with Syphilis, p. 104.

<sup>\*\*</sup> Mém. de la Soc. de chir., 1857, vol. iv, p. 125 (quoted by Keyes).

|| Lettsomian Lectures, 1888, quoted by Morrow. Loc. cit., p. 264.

the exudation, though at times considerable, has not become highly organized, and will yield with no great difficulty to other forms of treatment than cutting.

3. The tough strictures are easily demonstrated as such, passable with difficulty by a bulb that is not decidedly smaller than the contraction, and transmitting a distinct impression to the touch of their unyielding character and of the advanced state of organization of the plastic exudation.

We may as well add here that to determine accurately in doubtful and advanced cases the state of the urethra, narcosis is essential; or, to put it in another way, where a cutting operation is contemplated narcosis should be insisted upon; in short, if we are unable to assure ourselves that a cutting operation is not demanded, anæsthetization should be invoked to settle the question. Again, we have already noted that we may have any variety or all varieties of stricture in the same urethra, and that there is no limit to the number of the same kind, or of different kinds, that may obtain in a given case. An acute inflammatory process is a strong contraindication to any instrumental examination. The location of the lesion (or lesions) is another important factor in the treatment. In a general way, we never do an internal cutting operation posterior to the anterior layer of the triangular ligament unless we are also going to follow it immediately by a perineal operation. At the meatus, or within an inch of the meatus, we usually employ a blunt bistoury, putting the parts on a stretch with the dilator, or a bulb, or a sound, and we have never found it necessary to completely divide the meatus down to the frenum. In justice to the methods about to be given, let me say that no one looked upon divulsion with more distrust than did I at one time, because I had been taught that it was inaccurate, unsurgical, and unscientific; and yet, in the face of repeated successes in the hands of others, and later in my own, it is but fair to give the result of that experience. While I have employed but one instrument in divulsions, there are others, doubtless, just as efficacious, although we naturally incline to the bridge that has given us a safe passage.

To take up, then, the treatment of strictures in detail, we may first emphasize the importance of absolute cleanliness in our instruments, of careful cleansing (with boricacid solution, 1 to 12, or Thiersch, 1 to 2) of the urethra, and of using as a lubricant some sterilized material (Lydston \* suggests R Hydrargyri bichlor., gr. ss.; cocain. hydrochlor., gr. v; liq. albolene, f \( \frac{7}{2} \) j-M.); in perineal operations, thorough irrigation of the bladder before and after operating. If a case demanding treatment offers in which a distinct contraction at or near the meatus obtains, we may, if we so desire, use a small olive-pointed bougie and map out in our minds the condition beyond; but we are not losing time if we relieve this patent source of trouble by an inferior incision, preventing the adhesion of the edges by inserting a pledget of iodoform gauze, lubricated by carbolized vaseline or the lubricant quoted above. When this has healed we may again carefully explore the urethra and determine the kinds and sizes of the strictures that demand further care-

Reflex or spasmodic contractions, especially at the site of the bulbo membranous urethra, are sometimes completely relieved by the meatotomy, and spasmodic contractions elsewhere are generally so relieved. If we find that we have a resilient or a pliable stricture, or both, we cocainize the urethra, after the urine has been passed and the urethra cleansed, by injecting twenty to thirty minims of a two- to four-per-cent, solution of cocaine, keeping the meatus compressed for five or six minutes. Then with the dilator (Powell's) we divulse the strictures, slowly turning our knob, releasing and then turning again, until we have brought the urethra up to or just beyond its normal size or until we know the constriction is torn through, this method applying to strictures situated anterior to the triangular ligament. That such strictures may be relieved in a measure-at times apparently completely-by the patient and long continued passage of graduated sounds, aided by massage at the seat of the exudation while the sound is in the urethra, we are well assured; and in the bulbo-membranous urethra it is our practice to rely upon such a method of treatment unless an external incision be demanded. The resilient strictures are less readily amenable to treatment by sounds, doubtless because it is difficult to use a sound of sufficient caliber to completely distend them. It is hardly necessary to add that the sound need only be introduced as far as is necessary to distend the stricture—i. e., where the constrictions lie wholly in the penile urethra the introduction of sounds into the perineal urethra is neither desirable nor expedient unless a reflex spasmodic contraction demands such a course for its relief.

To return to the divulsion: The after-treatment consists in having the patient wait six or eight hours before passing urine, or even using a carefully sterilized catheter for twentyfour hours, and in absolute restraint from other instrumentation for four or even six days, at which time a sound one or two sizes smaller than that to which the stricture has been divulsed is introduced, the same precautions as to cleanliness being observed. Thereafter, at intervals of a week for three weeks more, the same thing is done, and at the end of this time the urethra ought to be in good condition. The points of advantage in our experience have been less hemorrhage, less tendency to recontraction and to adhesion of torn edges and, consequently, less need for frequent instrumentation, and the fact that general anæsthesia is not necessary, or indeed any detention from business for more than twenty-four or forty-eight hours. On the other hand, if a cutting operation is necessary, as we have uniformly found to be the case with the tough strictures, whether we first use a Maisonneuve and follow it by a divulser, or use the (Otis) urethrotome alone or as a sequel to the Maisonneuve (in strictures of very small caliber), we refuse to operate without an anæsthetic. The same precautions as to asepsis are followed; the smallest strictures anterior to the triangular ligament are completely dividedand by this we mean our incision, always in the roof of the urethra, goes through the plastic exudation; spasmodic contractions are then eliminated; and firm fibrous strictures in the perineal urethra are divided by an external incision. A sound beyond the normal size of the urethra is

introduced into the bladder, and a catheter is introduced into the bladder through the perineal wound and left in situ after the bladder and urethra have been thoroughly irrigated. We have never found, in strictures of very small caliber, that packing the urethra with a dozen filiforms had any advantage over a single filiform gently and patiently introduced; indeed, with the many cases of retention that came under our observation at the Chambers Street Hospital there was only one in which a single filiform could not be introduced; and in this case, after a perineal incision had been made and the urethra opened, it was at least fifteen or twenty minutes before the operator could get any instrument into the bladder, and then a small probe was introduced, and, grasping it with artery clamps, the operator pushed these in, and, opening the jaws, pulled them out, thus facilitating the passage of a director and making the rest of the operation an easy matter. A filiform once introduced makes us complete masters of the situation. retention in the urethra for twenty-four hours is invaluable in effecting continuous dilatation, and often in cases that refuse operation affords a most serviceable means of temporary relief. Sir Henry Thompson \* even maintains that by continuous dilatation (using a gum-elastic catheter) he can in ten to fourteen days dilate a stricture from the smallest number up to the highest. One other point we have noted in regard to the filiform: The twisted, bent, and other ends have never proved to be of more service than the simple, straight, olive-pointed instrument.

The after-treatment in these cases has been to remove the catheter after twenty-four to forty-eight hours; not to pass any instrument (except for three or four days a soft rubber catheter through the perineal wound to draw off the urine) until the fifth or sixth day; then under cocaine anæsthesia to pass a full-sized sound, but one or two sizes smaller than the size to which the urethra was enlarged; then at intervals of four days for two weeks, six days for three weeks, and fortnightly for two or three months, pass this same-sized sound, at the end of which time the urethra ought to be practically well. We should not forget that the treatment has just begun when the stricture has been divulsed or incised. The fact that many men do an internal urethrotomy in the bulbo-membranous urethra is often attested by the infiltration, perineal abscesses, and other mishaps attending such a course. It is not necessary to add that we endeavor to employ the utmost delicacy in all urethral instrumentation. To endeavor to divulse the tough, cicatricial strictures is wasting time and is apt to break our instrument. If we discover that we have incorrectly diagnosticated the character of our stricture, having relieved several by divulsion, but find one not easily thus relieved, we should defer cutting until anæsthetization be possible.

It would be an easy matter to quote from our case books one or several cases illustrating each method proposed; it would be more satisfactory to demonstrate for yourselves the practicability of the lines we have followed—viz.:

- 1. When the symptoms point to urethral difficulties, accurately determine the conditions present, using for this purpose the hard-rubber olive-pointed bougies, of small size, or the bulbs of larger size, or the urethrometer (though the last named is by no means a necessary adjunct to our urethral armamentarium chirurgicum).
- If a contracted meatus or constriction within an inch of the meatus obtains, immediate meatotomy and a careful subsequent examination of the whole urethra.
- 3. For resilient or pliable strictures in the penile urethra, divulsion under cocaine; in the bulbo-membranous urethra, the passage of sounds and massage, and in aggravated cases perineal incision under general anæsthesia; and in either case anæsthesia is permissible.
- For tough (fibrous, etc.) strictures, urethrotomy (internal) in the penile urethra; perineal section in the bulbomembranous, always under an anæsthetic in either case.
- Careful and continuous after-treatment by the passage of sounds and massage at the site of the exudation while the sound is in the urethra.
- 6. In all cases, scrupulous cleanliness, a clear conception of the case from beginning to end, and a frank statement to the patient of what we propose to do.

## A NEW METHOD OF EXAMINING THE KIDNEY, ESPECIALLY FOR STONE.\*

BY CHARLES P. NOBLE, M. D., SURGEON IN CHARGE OF THE KEN-INGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

I desire to report to the society a short history of the case of Mrs. T., together with an account of an exploratory operation which I performed to enable me to examine her kidney, including the pelvis of the kidney and perhaps an inch of the ureter.

Mrs. T., aged thirty-seven years, mother of three children, enjoyed good health until six years ago. Since that time she has been more or less an invalid, and for the past six months she has been absolutely an invalid, unable to attend to her duties. The prominent points in the history are that she has had three well-marked attacks of hæmaturia accompanied by violent renal colic (so called), and that at least twice she has passed good-sized stones, the last one coming from the left kidney. In addition to this history of violent attacks of renal colic, she has suffered frequently with milder attacks of paroxysmal pain referred to the region of the right groin, and the pain being perhaps most acute just above the right trochanter major. Recently these attacks have been of daily occurrence and have been brought on when she was on her feet. She is usually, but not always, comfortable when in bed, but shortly after any attempts at walking the attacks of pain come on. The sexual organs are normal, with the exception of a trifling tear in the perinæum. The urine has been examined many times and has a very uniform composition. Its specific gravity has varied between 1.020, 1.013, and 1.018; it is acid, and contains pus, bladder epithelium, and ureteral epithelium, but none from the pelvis of the kidney. The urine from each kidney has been examined separately, the urine being obtained by means

<sup>\*</sup> Diseases of the Urinary Organs, eighth edition, p. 62 (1888).

<sup>\*</sup> Read before the Philadelphia County Medical Society, January 26, 1894.

of the ureteral catheter. Examined in this way, it has been found that the urine from each kidney is much the same, the pathological elements it contains being somewhat more marked on the right side. This difference, however, was distinctly marked with reference to the two sides. The urine from the left kidney has always flowed through the ureteral catheter freely and regularly; that from the right kidney has not done so. Upon two occasions the ureteral catheter remained in position upward of twenty minutes, and not more than one or two drops of urine flowed out. Upon another occasion, after waiting thirty minutes with the same result, suddenly a hundred and twenty minims poured out.

Taking all the facts of the case into consideration, the conclusion seemed fair that there was a stone in the right ureter, and that probably this was in the pelvis of the right kidney. Several attempts were made, both by Dr. Howard A. Kelly and myself, to pass a ureteral sound along the ureter toward the kidney. It was not possible to make the sound reach above the brim of the pelvis. It was therefore proposed that the incision be made in the loin for the purpose of examining the kidney and the upper portion of the ureter from above.

My experience in performing nephrorrhaphy for movable kidney after the technique of Dr. Edebohls has taught me the facility with which a movable kidney can be drawn out through an incision in the loin. So far as I know, no one has ever treated a non-movable kidney in this way. It occurred to me that this might be feasible, and that at all events an attempt judiciously made could hardly be a source of harm.

Accordingly, on the 12th of December I made the usual incision in the loin down to and through the circumrenal fat, exposing the lower end of the kidney. With the index finger the kidney was then separated from its connective-tissue attachments and gradually drawn down into and out through the incision, so that it was entirely outside. It was now a very simple matter to explore the kidney by thumb-and-finger pressure, and to made certain that it was in a normal condition. It was equally easy to examine the pelvis of the kidney and to determine that this contained no stone. Perhaps an inch of the ureter also was within reach.

As nothing abnormal could be felt, the kidney was replaced within the abdomen and the incision was sutured in the usual ways, buried silkworm-gut sutures being placed in the muscular layer, and superficial silkworm-gut sutures in the skin. No febrile reaction followed this operation, and, so far as the operation itself was concerned, the patient made an uninterrupted recovery. Unfortunately, the operation has produced no effect whatever on the symptoms, which are the same now as before it was done.

I report the case simply to bring before you this method of examining the kidney. From my experience in this case and in cases of movable kidney, I believe it will be a simple and safe matter in the hands of the skillful surgeon, who has had some experience in kidney work, to remove through an incision in the loin all non-suppurating kidneys having approximately the normal size, for the purpose of a careful examination. The procedure is certainly not one of much gravity, and when done under the conditions laid down should have no mortality. Tentatively I would recommend the adoption of this method of exploring the kid- nosed. Emetics were given, but without relief.

ney whenever the symptoms point to the presence of stone in the kidney or its pelvis, and when these symptoms are of sufficient gravity to invalid the patient. I feel confident that, as compared with the ordinary method of exploring the kidney through the depths of the incision in the loin, the kidney itself being largely or wholly above the level of the ribs, and imperfectly palpated because of its movability, or examined by means of a puncture with an exploring needle, there can be no question of the superiority of the method proposed and herewith reported.

Upon theoretical grounds this procedure would not be applicable in cases of abscess of the kidney. Under these conditions supposedly, the kidney would be fixed and not easily separated from its connective-tissue bed. Moreover, it would be enlarged, and, in addition to this, there would be the risk of rupturing the pus sac perhaps into the peritoneal cavity.

## A CASE OF INTUBATION OF THE LARYNX OF UNUSUAL INTEREST.

WITH SOME REMARKS ON THE MANAGEMENT OF SUCH CASES.

By W. M. SEWARD, M. D., VISITING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL DISPENSARY, CLASS OF DISEASES OF CHILDREN.

THE case of a girl, seven years old, of healthy German parents, was referred to me by Dr. A. A. Richardson. She had been sick for three days before my first visit-on November 29, 1893. The tonsils and pharynx were covered with false membrane; temperature, 100° F.; pulse, 112.

November 30th .- Doing well; temperature, 99.5°; pulse

December 1st .- In the morning she had a croupy cough, with some dyspnæa, which increased rapidly. I called again at 5 P. M. and found her cyanosed. The parents had called in Dr. George B. McCauliffe, whose residence was near by. He had his tubes with him, and, at my request, intubated at 6 P.M. This relieved the labored breathing and the cyanosis, but the patient was very weak. The temperature was 101°, the pulse 130, and the respiration 30. Steam inhalations were given. also calomel fumigations, twenty grains every three hours.

2d .- The patient had not recovered her strength so rapidly as I have seen in such cases, but was doing fairly well. The temperature was 101.5°, the pulse 128, and the respiration 28. Four drops of tincture of digitalis and a grain of ammonium chloride were given every three hours, with the effect of improving the pulse.

3d.-The temperature was 99°, and the pulse 108 and of good quality.

4th .- The patient was still improving.

5th .- The temperature and the pulse were normal.

6th .- I removed the tube; the patient breathed well and there was very little spasm.

7th.-She was very comfortable and took food well.

8th .- She was still improving and continued to gain until noon, when she took cold and was attacked with bronchitis and a recurrence of croup.

13th .- There was some dyspnæa, and the use of calomel fumigations and steam inhalations was begun again.

14th.-Dyspnœa was decided and there was suprasternal and epigastric recession.

15th .- The breathing was very labored and she was cya-

16th.—Dyspnea was increasing in the morning. Wishing to postpone operating the second time as long as possible, I informed the parents as to where I could be found. I called again at noon and found the cyanosis increasing. At 4 p. m. I introduced a fresh tube. The child was in a very poor condition when it was done, and she fell asleep at once, exhausted, and slept all night, except when coughing for a minute at a time

17th.—The color was good, the temperature 102°, the pulse 138, and the respiration 34, and there were moist râles over both lungs.

18th.—The tube was coughed out at 5 A. M. The patient was somewhat croupy, but the tube was left out.

19th.—The croup increased again, and the parents were instructed to call upon me at any hour if the breathing seemed dangerous.

20th.—The patient was cyanosed again, and intubation was performed at 10 A. M., with perfect relief.

21st.—She was very comfortable and took food well. She continued to improve until the 30th, when, at 3.40 p.m., I removed the tube for the third time. The patient breathed well for only an hour; then the croup returned and increased steadily.

31st.—In the morning the breathing was quite hard, and in the afternoon the patient was somewhat cyanosed. As she had gained some strength, I thought it safe to leave the tube out a while longer.

January 1st .- At 12.10 A. M. the father called for me and said that the child had been breathing harder since my evening visit, so he feared she would live but a short time. Twenty minutes later I intubated for the fourth time and none too soon. I did not use a gag, as there was no time to be lost, and I hardly expected the child to revive again, for she was not only cyanosed, but almost pulseless, and the eyes had the glassy appearance too familiar to men who intubate and who are often called after children are practically dead. (In January I was called to intubate, and the child stopped breathing when the jaws were opened. The tube was introduced quickly and artificial respiration was employed; this started normal respiration again, but there was only enough strength to last for a short time.) The child revived, breathed easily, and fell asleep in her father's arms after about a minute. Twenty minutes later the color was better and the pulse was improved by giving 0.01 of a grain of strychnine in thirty minims of whisky hypodermically. There was cedema of the lungs, as one would expect after a patient had been so nearly dead from inability to get

2d.—The lungs were clearing up, and there were râles only in the large bronchial tubes. The color was good, the pulse 130 and of fair quality, the temperature 101°, and the respiration 30. The child was allowed to drink only from a teaspoon whenever the tube was in.

3d.—The temperature was  $99^{\circ}$ , the pulse 108, and the respiration 28.

4th.—The temperature and pulse were normal. After this she was given whatever she wished to eat.

8th.—She was allowed to walk about the room, and from this time she sat at table with the family and ate what she wanted, and there was no difficulty in swallowing. She gained strength rapidly and spent her time in playing and doing fancy work.

16th.—I removed the tube again. There was still stenosis, but it was not so decided as before. Dr. Joseph O'Dwyer was present and advised me to insert the tube again before leaving, as he did not think it safe to leave it out. I introduced a fresh tube, for the old one required to be soaked in an acid solution

to dissolve the rough calcareous deposit that existed on its surface. It is best, in cases requiring repeated intubation, to remove the tube at least once a week and insert a fresh, clean one if necessary. Dr. O'Dwyer advises this.

17th.—The child was very comfortable and hearty and continued to increase in strength and flesh until the 24th, when I removed the tube for the fifth time and found that the breathing was better than it had been at any time before. Two grains of Dover's powder were given two hours before the tube was removed. This is very important, as it controls the spasm which is generally present. The tube had to be inserted again two hours later, as dyspnœa had gradually returned. At this time I inserted a tube made to order by George Ermold, with a greater vertical diameter of the head, to prevent the tube from pressing on the same tissues that the old one had rested on, and thus producing a tendency to the formation of granulation tissue or to ulceration. This tube was worn until February 1st, and then it was extracted, two grains of Dover's powder having been given two hours previously. After it was out the breathing was very satisfactory, except for the spasm after coughing, which was controlled by giving two grains of Dover's powder every four hours for twenty-four hours.

February 2d.—The child was very comfortable.

3d.—She had a severe spasm at night, and the father came for me to intubate, but after an additional dose of Dover's powder she breathed well again.

For the last two weeks the child has been taking potassium jodide, from four to sixteen grains a day. It may be thought that tracheotomy would have been less troublesome in this case. I know of a case, however, in which it was done because the tube could not be introduced, yet months after the patient was finally cured by reintubations after the tracheotomy wound had healed. In another case, in which I saw tracheotomy done after the tubes had been used for a long time, the patient died of pneumonia.

The chief points of interest in this case are as follows:

1. The time that elapsed from the first introduction of the tube to its last extraction—sixty-one days. It was out fourteen days and in forty-seven. 2. After the tube had been worn for a week or two there was very little difficulty in swallowing.

3. It shows that it is important to introduce a fresh tube at least once a week.

4. The patient is now well, and the tube has been out since February 1st.

### A NEW ELECTRODE

FOR THE UTILIZATION OF CURRENTS OF HIGH TENSION,

WITH AN ILLUSTRATIVE CASE.\*

By A. D. ROCKWELL, M. D.

Whenever it becomes desirable to influence by the galvanic current any internal organ or portion of the human body, it is frequently necessary, in order to achieve the best results that electricity is capable of giving, to apply currents of far greater strength than those usually employed, and indeed greater than it is possible, with the electrodes in common use, without producing injury to the skin and unbearable pain. Relatively to metals, animal tissue is, of course, a poor conductor, but, as compared with the epidermis, it is an exceedingly good conductor, and there-

<sup>\*</sup> Read before the Medical Society of the County of New York, December 25, 1893.

fore, in making use of percutaneous applications of electricity to the human body, we need consider no resistance except that of its outer covering, the skin. Of the various conducting materials, I know of none so satisfactory in overcoming this resistance as sculptor's clay. The comparatively slight resistance that the clay itself offers to the passage of the current must be attributed not alone to its moisture, but to the contained aluminum, which imparts to this material some of the conductibility of metal.

Fig. 1.-Rear view

The objection to clay is that it is dirty, and difficult to handle without soiling the clothes and person of both physician and patient. To overcome this difficulty and thus render available this most useful material for general electro-therapeutical purposes, I have devised the arrangements illustrated in the accompanying cuts. These electrodes \* are of a non-conducting material—hard rubber—and may vary from one to five inches in diameter. The bottom of the disc is covered with block tin. This is an

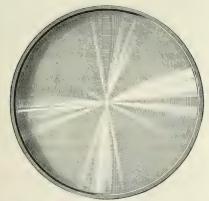

Fig. 2. Front view.

important feature, since, with the strong currents used, ordinary metallic conductors speedily become oxidized at the positive pole and their efficiency is impaired.

Block tin for all ordinary purposes is practically nonoxidizable. When wanted for use, the electrodes are

simply filled to the edges or a little beyond with the moistened clay and we have at command an electrode which permits the application of very strong currents without discomfort to the patient.

One who has been accustomed to use only electrodes of sponge, or absorbent cotton, or chamois skin will be surprised at the strength of current it is possible to administer through these contrivances.

With an electrode of this kind, two inches in diameter, one can readily bear from seventy-five to a hundred milliampères, and, on the well-known law that the greater the area the less the resistance, we have only to enlarge our electrodes to obtain with the same electromotive force an increased current strength, that is just as readily borne, since it is distributed over a larger area.

To illustrate the very remarkable results that it is sometimes possible to achieve in the suppression of pain and to show the especial value of the electrodes here described, I will relate a case interesting in more ways than one that was referred to me by Dr. Louis Sass:

The condition of this patient, a woman, had been diagnosticated by a number of eminent physicians in a neighboring city as one of "fallen spleen." Dr. Sass diagnosticated the condition as malignant, and with this diagnosis I concurred.

Dr. Joseph D. Bryant, at my request, made a most thorough examination of the patient, and not only diagnosticated cancer, but located it in the left kidney. With this diagnosis Dr. E. G. Janeway, who was further on requested to see the case, fully agreed, and subsequently Dr. Hermann M. Biggs, who had not seen the patient and knew nothing of her condition, made a thorough urinary analysis, finding among other things cholesterin crystals, thus confirming Dr. Bryant in his location of the disease.

Dr. Biggs thus writes: "The presence of cholesterin crystals in the urine is of exceedingly rare occurrence; only a few cases have been recorded in medical literature.

"They can only mean a degenerative process in the kidney associated with fatty metamorphosis.

"This has probably occurred in a malignant neoplasm of the kidney. The only case which I have seen (post mortem) was one of cystic sarcoma of the kidney."

When the patient came to my office, on the 24th of August last, she was suffering the most excruciating pain both day and night.

She had suffered in this way for nearly four months, and no effort had been made to relieve this suffering by any form of opiates. The use of electricity had been attempted, but in a way and by a method that aggravated rather than relieved her sufferings.

Beginning in the left side of the abdomen in the region of the enlargement, the dreadful pain—sometimes keen and cutting, at other times dull and aching, but never altogether absent—extended to the region of the left breast and shoulder blade. At her first visit clay electrodes, five inches in diameter, were placed one over the seat of the tumor and the other just under the left shoulder blade.

Very gradually the current was increased to seventy-five to one hundred, and finally to one hundred and fifty milliampères.

The result was little less than magical.

All pain disappeared for the first time in months, and for twelve hours she was entirely comfortable, after which the pain again began to appear.

<sup>\*</sup> Made for me by the Kidder Manufacturing Company.

It is unnecessary for me to go into the history of the daily treatment of this case. To every one except the patient the case was admittedly hopeless. She alone hoped on, for she could or would not associate such complete relief with an incurable disease, and in this belief she was not disturbed.

The patient grew weaker and weaker, and finally on the 15th of November passed away.

Unfortunately, no post-mortem could be obtained. For two months no day passed without the administration of the electrical treatment, and seldom without absolute and complete relief from pain. The interesting feature connected with the treatment is that mild currents had no effect over the pain. It was only when a hundred, and more frequently a hundred and fifty, milliampères were used that the distress was overcome. This is by no means an isolated case of the complete relief of pain in cases of cancer by the use of the galvanic current. The pain of scirrhous cancer of the breast is sometimes relieved just as completely as in the case just recorded, and with currents of far less strength. This is due to the fact that the diseased part is superficial and readily influenced by the current. When the locus morbi, however, is further removed from the surface of the body, rendering it impossible to get the electrodes in close proximity to it, it becomes necessary to use a far greater strength of current. The threads of current, so to speak, diverge so abruptly that parts but a little distance away, although directly in the path between the two poles, are but slightly influenced unless the current is very strong-far stronger than it is possible to obtain from the ordinary portable batteries, or that could be borne through the electrodes in common use.

# SUCCESSFUL REMOVAL OF GUNPOWDER STAINS.\*

By W. M. NELSON, M.D., C. M., SYRACUSE, N. Y.

The frequent occurrence of injuries to the skin by gunpowder explosion and the disfigurement that almost invariably results therefrom are, perhaps, sufficient excuse for my calling attention to a mode of treatment that has for its object the removal, more or less complete, of the carbon deposited in the skin and subcutaneous tissue, the which constitutes in the vast majority of cases the constant and permanent disfigurement.

Before going further, I may say that this paper will not deal with those slight degrees of injury where the carbon is not projected into the tissues, but simply lies partially imbedded in the epidermis and can be readily removed by the curette or spud.

The lesions the treatment of which I purpose to consider are those produced when the force of the explosion and the nearness of the victim entail the forcing of particles of carbon into the true skin and subcutaneous tissue.

Those who have been called upon to treat these lesions must have remarked that the "grains of powder" spoken of in text-books have been conspicuous by their absence, and that that which is found is an impalpable powder suspended at first in the blood and serum and then becoming imbedded in the tissues, and efforts to remove any of it that is not superficial by curetting only serve to drive it deeper.

The carbon is non-irritant, or nearly so, and, should no other foreign body or bodies accompany it into the tissues, there is no pus formation, no perceptible loss of tissue, and the injured part soon regains its original condition in every particular but that of color—more or less staining, analogous to that produced by tattooing with gunpowder, India ink, etc., remaining. The stain caused by the lodgment of black particles in the derma and underlying tissue is always of a blue color; this is explained by the fact that the color particles are viewed by transmitted light through the transparent epidermis and a portion of the corium.

In recent lesions and tattooing the carbon is diffused, but it soon becomes fixed in the lymphatic ganglia, subcutaneous tissue, and slightly in the corium. The particles that merely lie on and in the epidermis are thrown off by unassisted Nature.

The question of the possibility of removing carbonaceous staining has never received a great deal of attention, probably for the reason that tattoo marks are usually situated on covered portions of the body and limbs, and that accidental gunpowder marking has been looked upon more as a gentle reminder of an escape from serious or fatal injury than anything else. The fact also that the stains seldom amount to more than an unsightliness is doubtless another reason for this neglect; but that they are sometimes the starting point of skin lesions is shown by the case reported by Fox, of New York, of a tattoo mark of an anchor upon the lines of which twenty warts developed (American Journal of Cutaneous and Genito-urinary Discoses, vol. ii, p. 216). Keloid also has been known to follow tattooing.

The following are a few of the methods that from time to time have been vaunted as capable of removing these stains:

- 1. Fly blistering.
- 2. Vaccination.
- Tattooing in milk, enamel, tannin, acetic acid, lactic acid, oxalate of potassium, ten per cent. solution of nitrate of silver.
  - 4. Electrolysis.
- Incisions, under antiseptic precautions, planned so as to include as many points as possible.
- 6. Variot's plan. This consists in pouring over the marked spot a concentrated solution of tannin which is worked into the skin by deeply pricking it with a multiple needle; then the part is firmly rubbed with a stick of silver nitrate and the solution of the salt allowed to remain until the prick marks show out as black points. The part is then wiped off, and the result is the formation of a black stain of the tannate of silver. Considerable inflammation

<sup>\*</sup> Read before the Medical Society of the County of Onondaga, N. Y., December 19, 1893.

is set up, and in the course of a fortnight scabs form, on the disappearance of which no trace is left of the original mark, but only a reddish scar that fades with time.

7. Retattooing with glycerole of papoid.

Of all these methods of treatment, only the last three are worthy of consideration, and, in my humble estimation, that by the glycerole of papoid is the best. Removal by incision can only be carried out in selected cases, and is always followed by scarring.

Variot's plan is painful, sometimes dangerous from the intensity and extent of the inflammation produced, and at all times means an unsightly patch or patches, which persist for a lengthened period and are followed by indelible scarring.

The use of glycerole of papoid for the removal of tattoo marks was first advocated by Dr. Ohmann-Dumesnil, of St. Louis, in the New York Medical Journal of May 20, 1893, but, so far as I know, this is the first time his method has been applied to staining caused by gunpowder explosion. My experience with it I will now relate, and at the same time exhibit the individual upon whom it was carried ont.

On the 4th of last July the son of a prominent minister of this city was brought to my office suffering from injuries received from the premature discharge of a small cannon. I learned from the father and the physician who accompanied the boy that the cannon had been so overcharged and tightly rammed that when the charge exploded it forced its way through the vent instead of the muzzle, and into the boy's face, The condition of things found was as follows: Forehead, nose, anterior halves of cheeks, chin, eyelids, conjunctivæ, helix, anthelix, fossa of helix, and lobule of each ear densely studded with particles of carbon. In many places the force of the explosion had torn the skin, and in the tears were masses of carbon, in a state of fine division, ranging in size from a small pea downward. There was also some burning of the first and second degrees. Altogether it was the most marked case of facial staining by gunpowder I had ever seen. I curetted all parts that permitted of my doing so and endeavored with this small instrument (Piffard's comedone extractor) to express as much of the carbon in suspension as possible. The father was informed that a great deal of permanent staining would result despite any efforts made on the old lines of treatment, but that with his permission I would carry out the method recommended by Ohmann Dumesnil for the removal of tattoo marks. Consent was readily given, and on July 5, 1893, I commenced tattooing with glycerole of papoid and completed the process two days later.

The glycerole produced no irritation (in fact, there was a remarkable absence of it), the lesions scabbed over, and when I left for my vacation on the 11th of July the face was almost healed and all stains apparently fading away. I did not again see the patient till September 9th, and he received no further treatment.

As you see, there are only three minute stains left: that on the eyelid was not treated with papoid, as the curetting and pricking produced so much inflammatory ædema that I concluded to reserve the spot for another occasion.

I volunteered to remove the present minute stains with papoid or electrolysis, but the patient and family consider them of no consequence, and are entirely satisfied with the present condition of things. In conclusion, I may say the treatment is an empirical one, and I can not explain or describe what takes place after the introduction of the papoid.

Dr. Ohmann-Dumesnil's statement that the papoid is disseminated about the deposit of pigment and liberates it (this liberation, I suppose, is brought about by the digestion of the albuminous envelopes of the carbon particles), that a portion in a finely divided state is absorbed by the lymphatics, and the rest finds its way to the upper layers of the skin, thence to the surface, is a plausible but not altogether satisfactory one.

Some time in the future I hope to report the result of experimental work now under way.

406 WARREN STREET.

## REPORT OF A CASE OF PRIMARY SARCOMA OF A CHILD'S LIVER.

By E. R. AXTELL, M. D.,

DENVER, COL.,
PROFESSOR OF HISTOLOGY AND BACTERIOLOGY
IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER;
NEUROLOGIST TO THE DEACONESS HOME HOSPITAL;
PATHOLOGIST TO ST. LUKE'S AND TO THE ARPABOR COUNTY MOSPITALS.

The odd things with which a pathologist meets are not necessarily of great importance to medical literature, but the knowledge of their existence may make us a bit more cautious, a bit more accurate, and, because of this, better diagnosticians.

The following case is not exceedingly rare, but sufficiently so for record, and especially as it was carefully studied:

G. B. P., aged three years and a half, was born in Colorado, of strong and healthy parents. In the family there is no history of consumption, deformed members, or tumors.

The patient is a full-term child. The labor of the mother extended over a period of sixteen hours and the birth was fairly easy. When the patient was sixteen months old he had while teething one severe spasm. Two months later he had whooping-cough, and during this he had another severe spasm.

On several occasions he has had slight attacks of croup. Otherwise he has enjoyed good health, without being very robust. The symptoms of the present trouble date from the latter part of June, 1893. For three weeks he had a continued fever, which was thought to be either a mild typhoid or a simple catarrhal enteric fever. He then was able to be up and about. Soon after this, while playing with a playmate, he quarreled about a small hatchet and got quite angry. During this spell he began holding his breath, which he had a habit of doing. While thus holding his breath his mother noticed him fall backward, apparently unconscious and very pale. She picked him up and he recovered his breath and consciousness.

It is not known whether he was struck with the hatchet.

From that time his mother noticed a swelling in the epigastrium that was hard and round.

Soon, within two weeks at least, he began to have ascites. This was not recognized by the attending physician, who began to pass a catheter and later a rectal tube to reduce the size of the abdomen.

The fluid at last completely distended the abdomen, and on August 15th he was tapped and a full wash basin of fluid was withdrawn. For ten days the opening discharged the fluid and it then healed up. Immediately it began to reaccumulate. He was tapped the second time September 20th, or five days before the taking of this bistory.

Eleven days ago he began to cough. The cough has been dry and slight.

Ever since his continued fever he has been progressively running down in weight, strength, and vitality.

Appetite now capricious and poor. Bowels regular. Stools thin, soft, and light in color. Pulse, 156; temperature, 99.5° F. No history of chills.

The result of the physical examination made September 25th was as follows: In the left half of the epigastrium and in the left hypochondrium there is a hard, round, smooth mass, not movable, of the size of two fists. This mass is dull on percussion, gives no pulsation, no thrill, and no fluctuation.

Abdomen greatly distended. All signs of fluid in the dependent parts. Superficial veins of abdomen distended. Patient greatly emaciated. The respiratory sounds are clear on the left side, but bronchial over the base of the right lung The heart's area is increased; its apex is raised. The heart sounds are distant and muffled, but are apparently normal.

Uranalysis.—Urine of a dark amber color, of a strong urinary odor; specific gravity, 1'024; acid in reaction; no albumin to heat or nitric acid; no sugar; no special microscopical features. A faint reaction was obtainable to the test for bile salts.

From the examination, the diagnosis in the case was not difficult. Some tumor mass was present in the abdomen, and the portal vein or its radicles were pressed upon. As to the nature of the mass no positive diagnosis could be made.

Was it a fibroma, an aneurysm, a hydatid cyst, an adenoma, a cystic left kidney, a dermoid cyst, a sarcoma of the liver or kidney, a carcinoma, or a fæcal mass?

As the prognosis was very bad, the diagnosis was postponed. On September 30th the patient died at St. Authony's Hospital, where two hours later I was permitted to make a postmortem examination. On opening the abdomen, two quarts and a half of clear, dark amber, odorless fluid escaped. The peritonseum was found normal.

On opening the pleuræ, both were found to contain the same dropsical fluid, but neither was seriously distended.

The pericardium was completely distended by the serous fluid. This hydropericardium was undoubtedly the immediate cause of death. The heart lay almost vertically under the third and fourth ribs. The apex lay at the outer end of the fourth costo-sternal cartilage.

The heart was of fair size, the ventricles were normal in thickness, and the valves were perfect. In the right ventricle there was a small heart clot. The blood of the body was otherwise fluid.

The left lung was found anæmic, but otherwise it was fairly normal. A few patches of emphysema were found over the surface. All parts of the lung floated on water.

The lower lobe of the right lung was solid and presented all evidences, except pleurisy, of croupous pneumonia. The upper lobes of this lung were quite ædematous.

The spleen was small but normal; the intestines, the stomach, and both kidneys were normal.

The liver proved to be the seat of interest. It was greatly enlarged and presented some perihepatitis on its posterior surface. It weighed three pounds and ten ounces—more than the normal adult liver. The entire upper two thirds of the liver presented no hepatic structure, but was thrown up in three tumor masses. One sprang from the left lobe and pressed the diaphragm and heart upward; one came anteriorly from the left border of the right lobe. This mass was the tumor, the size of double fists, found on the physical examination in the epigastrium and left hypochondrium. The third mass was

found projecting from the right lobe, which lobe was but a mass of new tumor material. This tumor projecting was the smallest of the three masses. In the lobus Spigelli, at the base, there was a node of infiltration, and here and there, in the apparently normal hepatic tissue, there was serous infiltration. The mass on the upper surface was tense, whitish yellow in appearance, and sharply defined from the normal liver tissue.

The tumor mass projecting anteriorly gave evidence of fluctuation, and, on section, two or three ounces of dark grumous fluid escaped.

Section of the tumor in any part, except the recently infiltrated areas, revealed a dark-brownish, red mass, with here and there yellowish or creamy patches, due to fatty degenerative changes.

In the more recent and infiltrating areas the section was a light pink, studded with small red, brown, and yellow points hæmorrhagic patches in various stages of alteration.

Nowhere in the mass were found any well-defined connective-tissue trabeculæ.

The gall bladder was small, but uninvolved by the tumor. It contained some bile, which could be expressed from it into the duodenum.

From the naked-eye appearance of the tumor sections, the diagnosis of sarcoma was made.

Later, microscopical sections of various parts of the infiltrating mass showed it to be a small round-celled sarcoma.

No tissue like involuntary muscle could be found in any section, as is sometimes found in these early sarcomas.

## A NEW FORM OF ABDOMINAL BANDAGE FOR USE AFTER DELIVERY.

By A. HRDLICKA, M.D.

A part of the necessary attention to a delivered woman consists in the long-use-sanctioned and in many cases undoubtedly useful abdominal bandage.

It was invented with the view of supporting the relaxed abdominal parietes after a childbirth, and it was found not only to do this, but also, when properly applied, to exercise a beneficial pressure on the puerperal womb during the first week of its involution, stimulating it to keep up or increase its contraction.

These are uncontested advantages in an abdominal bandage properly applied and held in place; its theory is absolutely correct; but in practice, as any observer with even a limited field of work must admit, it generally falls short of these aims for various reasons, and has on that account been almost discarded by some physicians.

The material used for these bandages up to the present time, as we all know, has been bleached or unbleached muslin, applied either complete or partially cut on each side as a tail bandage. The application itself is made as soon as possible after the removal of the placenta, and with this begin the difficulties of the present bandage. The semi-exhausted woman, whose pelvis and back are in a condition compatible only with completest rest, must elevate her pelvis or have it elevated—which is still worse—so that the bandage may be slipped under. This done, we pass to another difficulty—the proper fastening of the bandage in front. Our purpose is to apply an even pressure all over the abdomen, and this with the most common, complete bandage is

well-nigh impossible; with the tail bandage it is much easier, yet not even here is the matter so simple as it would appear.

Having succeeded in applying our bandage perfectly, the first thing we see at our next visit to the patient is that it has slipped off, forming a mass of distressing wrinkles under the back and having all its pressure relaxed; or, if we applied the bandage low enough to avoid this, we find it soiled so much that we ourselves must unfasten and take it off. And the second application causes more inconvenience, as a rule, than the first.

Having all these difficulties in view, I have tried to replace the old bandage by something that, possessing the same or probably greater advantages, would not have these drawbacks, and I think I can safely say, though the extent of my experience hardly warrants it, I have succeeded.

I have had a case of oblique presentation in which, after delivery, the uterus retained an oblique position, the fundus lying entirely on the right ilium; there was a history of an injury affecting the region of the left broad ligament in the first part of gestation. I was able to reduce the uterus to the normal position manually, but, as soon as my hand was withdrawn, it returned, giving rise to local pains and distress. I ineffectually tried a compress and the usual bandage, and on my third visit resorted to a compress held in place by strips of adhesive plaster, and this worked to my perfect satisfaction, suggesting to me at the same time the entire replacement of bandage by adhesive plaster.

Trying it in practice since then, I have found it work admirably; it overcomes one and all of the disadvantages of bandages and effects more than the best of them.

Six two-inch strips of plaster usually suffice. They are cut of a sufficient length to pass over the abdomen from one to the other of the quadrati lumborum muscles. Over the surface of the abdomen a thin layer of cotton is laid, leaving about four inches on each side for the plaster to adhere, and if advisable in uterine atony or required from some other reasons, a suitable pad is put on the cotton and then the strips are applied over it, beginning with one over the compress. The woman is spared the slightest motion. There is no soiling, no possible infection as from unsterilized muslin, the plaster adheres perfectly and serves its purpose better than the most carefully applied of bandages could do, and it can be removed or reapplied with the greatest ease, not interfering in the least with abdominal examination.

I hope my little invention will attract the notice of my professional brethren. I do not know but some one may have employed the same before me; in that case I would join my humble voice with his and recommend the adhesive-plaster bandage heartily.

Change of Address.—Dr. William N. Hubbard, to No. 17 East Thirty-eighth Street.

# TO SECURE ACCURACY OF DOSAGE WHEN PRESCRIBING BY "TEASPOONFULS,"

BY LOUIS FAUGERES BISHOP, M.D., attending physician, department for diseases of the nervous system, demult dispersary.

EVERY one must have been annoyed by the irregularity of dosage when using the good old formula, "a teaspoonful three times daily," due to the personal equation on the part of the patient in selecting a spoon and in filling it when selected.

Many and obvious as are the ways of avoiding the teaspoon in medicine, it is certain to remain on account of its convenience.

I have hit upon the following plan, which satisfactorily overcomes the inaccuracy of dosage without banishing the spoon:

Before prescribing I ask the patient to select from among the spoons in my office one resembling that which he habitually uses. Then I hand the patient a four-fluid-ounce graduate and a bottle of water or of any handy fluid that is of about the same specific gravity as the medicine I intend to prescribe. Now the patient is instructed to pour out doses and place them in the graduate. When the fluid doled out reaches one or two fluidounces I stop him, and write my prescription on the basis of five, six, seven, eight, or nine doses to the fluidounce, according to the number of doses to the fluidounce he has placed in the graduate.

I have been surprised at the constancy of the personal equation in this simple operation in each individual, and at the wide difference between individuals.

In one case (that of an epileptic), in a prescription to last two weeks, the variation in the number of doses he gets out of it is only two or three, representing a variation of average dosage for separate periods of two weeks of only one tenth of a grain of the bromides which he is taking.

THE OAKDALE, 36 WEST THIRTY-FIFTH STREET.

The late Professor Billroth.—At a recent meeting of American physicians in Vienna the following resolutions were adopted:

Whereas, The hand of death has fallen on our profession, and we are called upon to mourn the loss of one of its greatest leaders, in behalf of the American physicians in Vienna and at home be it

Resolved, That in the death of Professor Theodor Billroth we recognize an irreparable loss, not alone to the physicians of Europe, but to those of the world.

Resolved, That in this termination of his laborious, worthy, and brilliant career the members of his profession have lost one of their most conscientious and honored coworkers, one whose death they profoundly deplore, and whose memory they venerate.

Resolved, That we extend to the family and to the faculty of the Vienna University our heartfelt sympathy, and assure them that these sentiments will be shared by every physician in our land.

Resolved, That we be represented at the funeral by a committee, and that a copy of these resolutions be presented to the family and to the faculty of the university.

# NEW YORK MEDICAL JOURNAL.

A Weekly Review of Medicine.

Published by Appleton & Co

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MARCH 3, 1894.

PROPOSED LEGISLATION IN FAVOR OF ACTING ASSISTANT SURGEONS.

WE lately expressed our hope that some means would be found to relieve those who served in the late war as acting assistant surgeons in the army-contract surgeons as they were commonly called-of certain obstacles in the way of their obtaining the rewards due them for meritorious and in some instances gallant services. How grievous these impediments are is set forth in a preamble to House Bill No. 5837 (Senate Bill No. 1594).

The preamble recites that before, during, and since the war of 1861 to 1865, but chiefly during the war, private physicians were employed as medical officers, serving under the orders of their superior officers as such, agreeably to Army Regulations, in the armies of the United States, in addition to the commissioned medical staff, because the number of the latter was not sufficient for the necessities of the service. These men were known officially as acting assistant surgeons, and they performed exactly the same duties, and were subject to the same control as commissioned medical officers. They were employed under contract made in accordance with paragraph 1268, Revised Regulations of the United States Army, 1861, and paragraphs 1304 and 71, Appendix B, Revised Regulations, 1863, and were obliged to remain in the service of the United States for a stated time. Among these officers were many of the eminent physicians and surgeons of the United States. Some of the duties performed by acting assistant surgeons were as follows: They were in charge and command of United States military hospitals, known as general, division, field, and post hospitals; they had charge and command of United States military hospitals for the care of contagious diseases; they were in command or in charge of hospital trains, hospital boats, and ambulance trains, and were executive officers of United States general hospitals; they acted as brigade and regimental surgeons, and at least one acting assistant surgeon acted as medical director of a department for nearly a year; they were responsible for hospital funds and property, and also post funds; they served on courts-martial, which the Articles of War require shall be composed of officers, and also on boards of survey, in camp, field, and garrison, on overland expeditions, and in Indian wars; they faced death and endured hardships like commissioned officers, and it is known that nearly one hundred and fifty died in the military service of the United States.

They were allowed fuel, rations, quarters, and transportation in kind, could purchase rations from the commissary, were allowed traveling expenses the same as commissioned medical officers with the rank of first lieutenant, and were accorded, by | bacteriologists the instructors in obstetrics of our colleges have

order of the War Department, the same protection in their position, the same respectful subordinate conduct, and the same military courtesy from enlisted men as if they were commissioned officers, because they were placed in the position of commissioned officers so far as related to their duties. Many of them were also required to wear the uniform of an assistant surgeon. Acting assistant surgeons who were disabled by reason of disease contracted or injury received in the military service have been granted pensions under a law which assimilates them to the rank of first lieutenant of the military or Marine Corps.

But because they were not commissioned as officers, but were employed by contract as such, they are denied admission to military organizations like the Loyal Legion and the Grand Army of the Republic; and to relieve this unjust discrimination, and to give a proper recognition to their patriotism, duties, responsibilties, services, hardships, and exposures, they ought to be entitled to receive the rank for which they are allowed pensions and which will relieve them from these disadvantages.

The bill provides that private physicians who were employed as medical officers in the armies of the United States for a period of not less than three months, in accordance with the Revised Regulations, United States Army, who were known officially as acting assistant surgeons of the United States Army, and whose services were honorably terminated, shall be commissioned by the President of the United States as acting assistant surgeons of the United States Army; the date of employment as acting assistant surgeons to be the date of commission and muster into service, and the date of the honorable termination of service as acting assistant surgeons to be the date of discharge or muster out of service. It is stipulated that no pay or allowance shall be made to any such acting assistant surgeon by virtue of the act, and that the act shall not affect the rank, pay, or emoluments of commissioned medical officers of the United States Army.

We presume that the bill is not intended to apply to those who have taken contracts since the close of the war, but it is not so stated specifically. . Be that as it may, we are convinced that the passage of some such bill would be no more than an act of mere justice to a deserving set of men, and we hope that Congress will so view the matter.

### GROSS CLEANLINESS IN OBSTETRICS.

A VERY startling statement has recently been published to the effect that the introduction of the doctrines of antisepsis and asepsis into obstetric literature and teaching has not materially lessened the mortality of childbed outside of hospitals. The reason alleged is that the doctrines of minute (or, if we may term it so, "microscopic") cleanliness have not taken hold upon the minds and conduct of the mass of private practitioners.

Can it be that by following too closely the teachings of

overshot the mark-have got too far in advance of the average medical student? It is possible that the young graduate from such teaching may fall into one or the other of two grave errors when he is brought face to face with the hurry and worry of busy practice, with the prejudices of parturients and with the innate or acquired uncleanness of the, perhaps diplomaed, grannies of various ages whom he classifies at once by the dirt under their uncut finger nails. He may either despair altogether of asepsis and give up not only the use of the nail-brush but even the thorough washing of the hands in soap and water before vaginal examinations, or be betraved into thinking that the dipping of the hands into antiseptic solutions, so feeble in percentage of antiseptic salts and so slightly applied that they do no good, will take the place of thorough scrubbing with soap and water, of cleanliness in clothing, and of neatness of personal habits.

It might be well to have in our medical schools two courses of lectures on obstetrics, one embracing the highest scientific teachings of applied bacteriology concerning the best methods of germ destruction, the other giving certain plain practical lessons in ordinary midwifery, including simple rules of cleanliness such as the most careless graduate might be expected to comprehend and actually apply in practice. As distinguished from that "microscopic" cleanliness which involves the wearing of white robes, the scraping of the finger nails with sharp implements, the soaking of the hands in successive chemical solutions, the irrigation of the mother's parts with antiseptic washes in ordinary labors, and the closing of the vulva with antiseptic cotton pads, this "gross" cleanliness would include the wearing of clean underclothing upon the arms by the physician and nurse, the thorough washing of hands (and in operative cases of the arms to the elbow) with soap and warm water and the careful use of a nail-brush, whenever the genitals were to be touched, the washing of the vulva by the nurse before each examination or series of examinations, and the cleansing of all instruments which were to be used.

While "microscopic" cleanliness should be maintained in hospitals and should be insisted upon by obstetrical teachers in all cases in private practice where the patient is thought to be infected before labor or where the doctor has been attending suspicious cases, this "gross" cleanliness should be carefully drilled by reiteration and example into students for use in private cases where no infection is suspected. Fatal sepsis following its neglect ought to be ground for legal prosecution of the practitioner. The reasons for dwelling upon these principles of "gross" cleanliness are very strong: First, they are sufficient in ordinary labor cases. Second, "microscopic" cleanliness is in many cases not attainable—the necessary appliances are absent and the mother and nurse think it needless and resent it. Third, in the absence of "gross" cleanliness "microscopic" cleanliness is inefficient. What, for instance, is the use of dipping the hands into antiseptic solutions when the finger, to reach the cervix, must pass through an unwashed vulva tainted with decomposing fæces, blood, and urine? Yet who ever heard an ordinary practitioner inquire whether the

parts had been washed before making a vaginal examination? It need hardly be added that "gross" cleanliness is just as much needed and, if possible, more neglected in cases of miscarriage which demand manual assistance.

# MINOR PARAGRAPHS.

THE RELATIONS OF OPIUM-EATING TO LIFE INSURANCE.

VERY few opium-eaters have any thought of insuring their lives-they do not concern themselves in regard to the futureand very few have the means with which to pay premiums on policies after their supply of the narcotic has been paid for. The Independent thus speaks of the opium investigation now in progress in India: "It has been stated that among the socalled evidence used by the government party to bolster up the pro-opium side, the Oriental Life Assurance Company, which does almost the entire native business of India, testifies that no extra premium is charged to users of the drug, and states that during twenty years not a single claim has been paid for death which could have been attributed to the use of opium. Granting that the statement is correct, we would like to know to what extent life insurance policies are taken out in opium dens in India. It is doubtless true that similar statements might be made with regard to policies paid to habitués of the dives of New York or any American city. It does not therefore follow that opium has no effect to shorten the life." It is a peculiarity of the testimony on the opium question that the witnesses who hold office in India are nearly all pro-opium, while the non-official class are almost unanimous in the other direction. This applies to medical witnesses as well as to others.

# TUBERCULOSIS AND BOARDS OF HEALTH.

As our readers are well aware, various important boards of health throughout the country have lately become exercised over the question of including tuberculosis among the infectious diseases that they require physicians and householders to report to them, and over the further question of what their authority, with due consideration of expediency, warrants their doing in cases reported. In some quarters rather arbitrary measures have been proposed-not actually carried out or resolved upon, so far as we are informed. An example of wholesome considerateness in this matter has been set by the Michigan State Board of Health, a body that has always wisely inclined to achieve public sanitation rather by spreading sanitary education among the people than by harsh interference in household affairs. On the 30th of September the board adopted a resolution to the effect that thenceforth consumption and other diseases due to the Bacillus tuberculosis should be included in the official list of those that householders and physicians were required to give notice of to the local health officers as soon as the nature of the disease was recognized in individual instances. In a circular announcing the adoption of this resolution, for a copy of which we are indebted to the board's excellent secretary, Dr. Henry B. Baker, attention is directed to the fact that the question of the patient's isolation is not mentioned in the resolution. Its purpose, the circular goes on to say, is to secure to the local health authorities and to the State board information of the locality occupied by each person affected with tubercular disease, with the view of giving him trustworthy information as to how he may avoid reinfecting himself and infecting others, and telling persons most endangered how to avoid contracting the disease.

#### THE CHARITIES OF LONDON.

According to the nineteenth annual Directory to Metropolitan Charities, over \$27,000,000 are spent in a year in carrying on the work of 759 societies and institutions. Of these latter there are 206 in which the medical profession is interested. Their respective number and object, together with their income stated in English values, are given in the following paragraph:

"Twenty-five charities for the blind, £74,299; seven charities for deaf and dumb, £20,565; five charities for incurables, £51,527; two charities for idiots, £59,165—£205,556. Sixteen general hospitals, £351,247; eight consumption hospitals, £70,235; five ophthalmic hospitals, £15,876; three orthopædic hospitals, £5,462; five skin hospitals, £8,487; sixteen hospitals for women and children, £88,825; four lying-in hospitals, £13,942; twenty-nine miscellaneous special hospitals, £11,884—£673,958. Twenty-nine general dispensaries, £29,083; thirteen provident dispensaries, £9,321; six institutions for surgical appliances, £38,599; twenty-six convalescent institutions, £64,-449; seven nursing institutions, £11,708—£153,160."

The orphan asylums, diet dispensaries, and homes for aged persons are not included in the summary above given, but their income is very liberal and they are fully a hundred in number.

### AN ABORTIVE TREATMENT OF QUINSY.

In the February number of the Annales des maladies de l'oreille, du larynx, du nez et du pharynz there is an abstract of an article by M. Liégeois, published in the Revue de clinique et de thérapeutique. The author states that he has succeeded in aborting an attack of quinsy between the fourth and sixth days in six cases by means of combined local and general treatment, At the outset he cauterizes the tonsil once by painting it with a solution of one part of zinc chloride in twenty parts of glycerin. The eschar separates in forty-eight hours. After the cauterization, a drachm of salol is to be taken in the course of twelve hours. The salol acts as an intestinal antiseptic, an antipyretic, and an analgesic.

## A NEW CLINICAL SOCIETY.

The staff of the Brooklyn Central Dispensary has organized a clinical society, for the purpose of holding a monthly interchange of views on medical and surgical subjects. Reports of the more important cases occurring at the dispensary clinics will be presented and preserved. The name of the organization is the Central Clinical Society of Brooklyn. Among the members are Dr. Barber, Dr. Lucas, Dr. Yorke, Dr. Anderson, Dr. Cochrane, Dr. Jelliffe, and Dr. Wood. The meetings will be held on the fourth Thursday of each month.

# NEW YORK STATE BOARD OF HEALTH.

The Albany correspondents of the daily papers have been writing concerning certain alleged defects of discipline and non-performance of work on the part of the board's clerical staff. They also state that Dr. Lewis Balch will resign his position as secretary and executive officer. Dr. Balch has been in the health service for ten years and upward, having succeeded the late Dr. Alfred Ludlow Carroll. The work of the board, under Dr. Balch, has been exceptionally strong in the direction of the water supply and drainage systems of numerous towns and villages in the interior of the State.

# THE KINGSTON AVENUE HOSPITAL, KINGS COUNTY.

The institution used by the board of health of Brooklyn, formerly known as the Contagious Disease Hospital, has had its name changed to the title above given. Consideration for the feelings of the unfortunates who are obliged to be treated for contagious maladies and be separated from their families, and consideration for those families as well, has been one of the motives for this change of name. Dr. Jesse T. Duryea, formerly a medical officer at the Kings County Hospital, will assume the superintendency of the Kingston Avenue Hospital about March 1, vice Dr. H. Bullwinkel.

## ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 27, 1894:

DISEASES.	Week ending Feb. 20.		Week ending Feb. 27.	
an and add and the	Cases.	Deaths.	Cases.	Deaths.
Typhus	()	0	0	0
Typhoid fever		4	9	2
Scarlet fever	129	14	134	12
Cerebro-spinal meningitis	4	4	2	1
Measles	499	27	430	31
Diphtheria	170	49	188	61
Small-pox	23	3	37	9

The late Dr. Michael K. Hogan.—At a special meeting of the medical board of St. Vincent's Hospital, held on the 26th of February, 1894, to take action on the death of Dr. M. K. Hogan, the following minute was adopted:

The members of the medical board of St. Vincent's Hospital, having learned with profound sorrow of the death of their highly esteemed colleague Dr. M. K. Hogan, on whose long and faithful service as attending physician, on whose rare ability, and on whose devotion to the sick poor all the officers and the sisters of the hospital bave placed the greatest value, have resolved to attend his funeral in a body, and, through the medical journals, to make known their appreciation of the high personal and professional character of their late associate.

[Signed.] J. A. MCCREERY, M. D., Secretary.

The Eleventh International Medical Congress.—We are requested to announce that Professor H. J. Johnston-Tavis, of Naples, will be pleased to 'aid and advise American visitors to the congress during their stay in Naples.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 18 to February 24, 1894:

TEN EYCK, BENJAMIN L., First Lieutenant and Assistant Surgeon, will report in person to Bally, Joseph C., Colonel and Assistant Surgeon General, president of the examining board appointed to meet at Fort Sam Houston, Texas, at such time as he may be required by the board for examination as to his fitness for promotion.

MOSELEY, EDWARD B., Major and Surgeon. The leave of absence on surgeon's certificate of disability granted is extended one month on surgeon's certificate of disability.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Four Weeks ending February 17, 1894:

MURRAY, R. D., Surgeon. To proceed to Key West, Fla., for special duty. January 26, 1894.

Ballhaohe, P. H., Surgeon. Granted leave of absence for twenty days. February 5, 1894. Purviance, George, Surgeon. Detailed as chairman of the board of examiners. February 12, 1894.

STONER, G. W., Surgeon. Detailed as member of the board of examiners. February 12, 1894.

Carter, H. R., Surgeon. To report at bureau for temporary duty. February 2, 1894. To proceed to Brunswick, Ga., Quarantine as inspector. February 6, 1894. Detailed as recorder of the board of examiners. February 12, 1894.

White, J. H., Passed Assistant Surgeon. Granted leave of absence for seven days. February 17, 1894.

CARRINGTON, P. M., Passed Assistant Surgeon. Granted leave of absence for thirty days. February 19, 1894.

Bratton, W. D., Passed Assistant Surgeon. Granted leave of absence for thirty days. January 20, 1894.

Pettus, W. J., Passed Assistant Surgeon. Granted leave of absence for thirty days. January 30, 1894.

VAUGHAN, G. T., Passed Assistant Surgeon. To report to the Secretary of the Treasury for special duty. January 26, 1894.

Young, G. B., Assistant Surgeon. Ordered to examination for promotion. February 14, 1894.

STIMPSON, W. G., Assistant Surgeon. Ordered to examination for promotion. February 14, 1894.

Brown, B. W., Assistant Surgeon. Ordered to examination for promotion. February 14, 1894.

ROSENAU, M. J., Assistant Surgeon. Granted leave of absence for thirty days. February 26, 1894.

COFER, L. E., Assistant Surgeon. To proceed to Mobile, Ala., for duty. January 30, 1894.

EAGER, J. M., Assistant Surgeon. Granted leave of absence for four days. January 30, 1894.

BLUE, RUPERT, Assistant Surgeon. Granted leave of absence for eight days. January 26, 1894.

NORMAN, SEATON, Assistant Surgeon. Ordered to examination for promotion. February 14, 1894.

PROCHAZKA, EMIL, Assistant Surgeon. To proceed to New York for duty. January 24, 1894. To proceed to Buffalo, N. Y. for temporary duty. February 2, 1894.

# Society Meetings for the Coming Week:

Monday, March 5th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private), New York; Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; Providence, R. I., Medical Association (annual); St. Albans, Vt., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

TUESDAY, March 6th: New York Neurological Society; New York Obstetrical Society (private); Elmira, N. Y., Academy of Medicine; Buffalo, N. Y., Medical and Surgical Association; Ogdensburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medicine; Medical Society of the University of Maryland and Baltimore; Essex, Mass., South District Medical Society (annual—Salem).

WEDNESDAY, March 7th: New York Academy of Medicine (Section in Public Health, Legal Medicine, and Vital Statistics);
Harlem Medical Association of the City of New York; Society of the Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton); Penobscot, Me., County Medical Society of Medical Society Medical Society Medical Society of Richmond

cal Society (Bangor); Bridgeport, Conn., Medical Association.

THURSDAY, March 8th: New York Academy of Medicine (Section in Pædiatrics); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

Fridax, March 9th: Yorkville Medical Association (private), New York; Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, March 10th: Obstetrical Society of Boston (private).

**Professor Eulenburg**, the newly appointed editor of the *Deutsche medicinische Wochenschrift*, we are informed, will not move from Berlin to Dresden, as was his intention of doing before assuming his editorial duties.

# Letters to the Editor.

BISMUTH POISONING.

Dublin, Ireland, January 27, 1894.

To the Editor of the New York Medical Journal:

SIR: The letter of Dr. N. L. Wilson in your columns of the 24th ult. suggests some questions as to a case which has caused a good deal of interest in America as well as in England-that of Mrs. Maybrick. Mr. Maybrick's symptoms corresponded to a large extent with those described by Dr. Wilson. In eight ounces of his intestines Dr. Stevenson discovered a grain and a half of bismuth to 0.015 of a grain of arsenic. In the liver, however, he estimated the proportions at a third of a grain of arsenic to a grain of bismuth. Arsenic, I believe, is often found in bismuth, and the bismuth given to Mr. Maybrick does not seem to have been tested for arsenic. It will be recollected, too, that a small quantity of arsenic had been administered by the attendant physician, Dr. Humphreys, who considered the effects beneficial; but Mr. Maybrick objected that it burned his throat, and his wife-the supposed poisoner-discontinued the use of it. He had been in the habit of taking considerable quantities of arsenic as a stimulant, but the evidence that he had done so shortly before his last illness was defective.

Another medical question connected with the case is relapse and exhaustion occurring after a dose of sulphonal.

A BARRISTER.

# AN IRRIGATING SPECULUM.

ROCHESTER, N. Y., February 14, 1894.

To the Editor of the New York Medical Journal:

Sir: In your issue of November 4, 1693, I described a new vaginal speculum (for irrigating and washing out the uterus and vagina), and in your issue of January 27, 1894, Dr. Talley describes one of his inventions which will answer for a part of the purposes for which Davis's will, and claims two days' priority. I am glad that Dr. Talley had the same idea without

knowing anything about my instrument, as it shows that such an instrument was wanting and that he deserves the same credit as though his instrument had been made before mine. While I was assisting in Professor Rokitansky's Klinik in Vienna, where such a large number of women came for local treatment, I saw the necessity for something to wash and irrigate the vagina and os uteri without wetting everything under the patient. And it was there I visited three surgical manufacturing houses, with H. Reiner at the head, and in the same way in Berlin during the year 1892, with H. Windler heading the list, with a negative answer. As my time was limited after returning home, I only had one made for my own use, but on August 28, 1893, I had Mr. George Ramsdell, of Rochester, make a woodcut of my instrument, and he gave me four impressions, which I mailed to Messrs, Ford, A. S. Aloe & Co., Sharp & Smith, and George Tiemann & Co., who all replied that they did not know of an instrument that would answer the same purpose and were willing to make it. After it was placed in the hands of the makers (Tiemann & Co.) I had a few reprints struck off and mailed to physicians I knew, and showed it at the Pan-American Medical Congress in the registration hall of the Willard House. Early in September I showed the first instrument made by Messrs. George Tiemann & Co. to a goodly number of Rochester physicians, and with their criticism and my suggestions it was returned to the makers. JAMES C. DAVIS. M. D.

### THE WEST-SIDE GERMAN DISPENSARY.

1244 Broadway, New York, February 19, 1894.

To the Editor of the New York Medical Journal:

Sir: At a special meeting of the Medical Board of the West. side German Dispensary, held on Saturday, February 17, 1894, it was

"Resolved, That the president be instructed to inform the New York Medical Journal and the New York Medical Record that the Medical Board of the West-side German Dispensary disclaims all knowledge of, complicity with, and responsibility in the articles which recently appeared in the daily press regarding occurrences in this dispensary. FERD. C. VALENTINE,

President of the Medical Board of the West-side German Dispensary.

# Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of February 1, 1894.

The President, D. B. St. John Roosa, M. D., in the Chair.

Preventive Medicine.—Dr. W. W. POTTER, of Buffalo, read a paper with this title. (To be published.)

Dr. A. Jacobi alluded to the legal means of suppressing contagious diseases. Communities were usually much opposed to the enforcing of sanitary rules. We should have to come to it certainly, for it was the only way in which such things could be controlled. The general welfare was of more importance than individual right or personal comfort. The family physician was the person from whom the greatest good could come, in the way of educating the people by teaching them individual hygiene. Many diseases would not take hold of persons in perfect health. They could not have tuberculosis, diphtheria, cholera, and so forth, so long as their mucous mem-

branes were healthy and intact. The whole mucous membrane of the respiratory and alimentary tract was covered with epithelium which, if sound, crowded off any bacilli that found lodgment there. One of the first things to be done in a family was to correct all catarrhal conditions, not to allow colds to go on, and, if children had hypertrophied tonsils, to attend to them-leave no diseased membrane upon which diphtheria could take hold, and you had destroyed the most fertile field of that disease. It was rather hard to control those sources of danger, because many heads of families objected to having their children's tonsils removed or their noses burned out. There was no doubt that we all lived in an atmosphere of tuberculosis, but so long as our mucous membranes were in a healthy state we were safe from the disease. It was the same with cholera and typhoid fever. What was needed was individual effort in educating the people to understand the importance of assisting the physician in preventing dis-

Dr. J. West Roosevelt dealt with the question from its legal aspect. He thought that the first persons who needed instruction as to what was wanted to procure immunity from disease were the physicians. The medical profession would have no difficulty in getting legislation on a question when they found out what they wanted, but the trouble would be to get them to abide by the rules laid down. It was all very well to preach to people, but the physician would have to look at home first and think how he would act in the event of his having tuberculous friends or relatives who would have to come under some stringent sanitary rule. In an attempt to stamp out tuberculosis, if one thought of the whole ground that would have to be covered, the task seemed almost too stupendous and hopeless to undertake. It must be remembered that if a law was made that could not be enforced and had to be repealed, it would give to the advancement of preventive medicine a most serious setback.

Dr. S. S. Burr said that he agreed with the writer of the paper in believing that the most important part of medicine was undoubtedly preventive. We could not legislate for people that did not want legislation, consequently it was the duty of the physician to teach them what they wanted in the way of preventing disease. The pathologist was finding out what diseases were, and what would prevent or kill the germs, but this was not all that was to be done; patients could be got into such shape that they could resist disease-producing elements. Just now no such thing was expected as the killing of all disease germs, but attention was directed to fortifying patients against their onslaught. The best way of preventing disease was to educate the people to an understanding of their condition. We were constantly surrounded by tuberculosis, and the best way to prevent taking it was by keeping ourselves in the best possible shape and by so directing people whenever they came under our care. Tell all patients to avoid expectorating tuberculous sputa on floors and streets, explain fully to them what it means, he said. He should not become discouraged if the outlook was not bright, but continue to work in a direction that would bring all diseases under control; one by one they were being crowded out. For example, small-pox was fast becoming eradi-

Dr. J. D. BRYANT referred to the work of the health board of New York and to what had been done by it during the past four years. He spoke of the bill presented by himself in relation to tuberculosis in cattle. It had been so drawn that a diagnosis was imperative, and, when that was made, the animal was to be killed and cremated. Of course the fight was still on, there was so much to contend with. Nobody wanted to lose his animals, even if he was remunerated. He thought that

the educational methods referred to would do much more toward the prevention of disease than any law that could be made until people were prepared for it.

Dr. Potter did not want to be understood as asking the academy to make laws, but he wanted to ask that it enter upon a campaign of education for the prevention of disease. It was to the academy that the out-of-town doctor looked for the directing element in any great medical undertaking, and it was only by their combined efforts and co-operation that the success of such a work could be hoped for. It must be borne in mind that it was not the highest function of the physician to give a dose of medicine, but to teach the prevention of disease. It was the special function of the academy to strengthen the power of the various health boards throughout the country, for much better work might be done by them if they were not so hampered by ignorance. Let it be considered the duty of the academy to see that all literature promotive of preventive medicine be freely distributed where it would do the most good, and by this means educate the people to a sense of their responsibility in preventing disease.

# Book Antices.

The Theory and Practice of Medicine. Prepared for Students and Practitioners. By James T. Whittaker, A. M., M. D., Professor of the Theory and Practice of Medicine in the Medical College of Ohio, etc. With a Chromo-lithographic Plate and Three Hundred Engravings. New York: William Wood & Co., 1893. Pp. xvii-3 to 821.

In the preface the author states that "in the preparation of this book the most work has been put upon the infections, as the most frequent and dangerous, at the same time the most preventable, of all diseases"; so, when we open the subsequent pages, we find that the first two chapters discuss the ectozoa and entozoa, presumably serving to carry the student's mind from the consideration of these grosser parasites to the microorganisms discussed in the third chapter. The latter would seem to properly belong to a work on bacteriology or perhaps to one on medical diagnosis rather than one on practice.

The entire first part of the volume is devoted to the various communicable and infectious diseases, and the author includes among the latter those whose clinical history suggests infection, although the respective causes of the diseases in question have not yet been discovered. Each disease is considered in a practical fashion that will, we think, be much appreciated by the student, especially the advice given in regard to treatment.

The second part of the volume is devoted to diseases of the organs of digestion, of the respiratory organs, of the circulatory organs, of the genito-urinary system, and of the nervous system.

The author states that he has intentionally omitted reference to the morbid anatomy of disease; but one can not help thinking that it would have been very useful to the reader to enforce the clinical picture by a description of the pathological changes.

It seems, too, that the author has frequently failed to do himself justice; his treatment of the subject of diseases of the nervous system is so condensed that this section savors more of a conspectus than of a text-book, and by no means expresses the extent of his familiarity with this topic.

We hope that in the second edition of this work, for its practical features and recent information will undoubtedly cause a second edition to be called for, the author will treat of his various topics with that greater elaboration of detail that we are justified in expecting from his scholarship.

Traité de médecine. Publié sous la direction de MM. Charcot, Professeur de clinique des maladies nerveuses à la Faculté de médecine de Paris, Bouchard, Professeur de pathologie générale à la Faculté de médecine de Paris, et Brissaud, Professeur agrégé à la Faculté de médecine de Paris. Par MM. Babinski. Ballet, P. Blooq, Brault, Chantemesse, Charrin, Chauffard, Courtois-Suffit, Gilbert, Guinon, Le Gendre, Marfan, Marie, Mathieu, Netter, Guinon, Le Gendre, Marfan, Marie, Mathieu, Netter, Guinor, Thionot, Fernand Widal. Tome IV. Par MM. Ruault, Brissaud, Le Gendre, Marfan, Netter. Avec figures en noir et en couleurs dans le texte. Tome V. Par MM. André Petit, Cettinger, Brault. Avec cinquante-six figures dans le texte. Paris: G. Masson, 1893. Pp. 1112, 906.

The system of competitive examinations obtaining in France, the successful passing of which is the sine qua non of all hospital as well as of university preferment, entails great respect being shown to the fortunate candidates. Their learning and mental qualifications for the post they are to occupy have become well known to their fellow-competitors, to the various juries, and even to the general public during the long years throughout which has lasted the struggle for what has proved the unattainable to the vast majority. The seal of their success assures the public that these men have acquired a vast deal of learning and a superior degree of the requisite skill in handling either a patient or a treatise, and that their long scientific training will guard them from errors arising either from ignorance or from forgetfulness. In all future topics discussed by these scientists the subject-matter will inevitably be duly marshaled and all opposing opinions stated without an undue personal bias. Moreover, these good soldiers will go through all the manœuvres in which they have been so patiently drilled without any display of awkwardness, even with the extreme ease that only long habit brings. But, as they are usually middleaged when finally freed from the rank and file, their spontaneity is dead, and, since it is now too late for the majority of them to undertake original investigations, they will continue as they have begun, becoming constantly more erudite and better clinicians. Hence the books written by such men are to be accepted as judicially correct, as containing no conclusions that have been warped by passion or distorted by ignorance. Ample information will be given on every subject, the style will always be good, the letterpress excellent, and the only thing their critic can do is to admire, perhaps without envying, a system that can produce such a large percentage of admirable workmen. All this is peculiarly true of the authors of the present volumes, who are indeed among the best known of the younger generation of the French masters.

The diseases of the respiratory and circulatory systems are discussed. The affections of the nose and throat are described by A. Ruault. The chapter on asthma is by E. Brissaud and that on whooping-cough by P. Le Gendre. A. B. Marfan studies the pathological conditions of the bronchial tubes, the chronic diseases of the lungs and of the mediastinum. Among the various types of bronchitis he mentions a subdivision of the pseudo-membranous, rarely described—namely, the acute fibrinous, of unknown origin, and the chronic pseudo-membranous. Among the diatheses supposed to be more or less influential in cutalling tuberculosis, we find Marfan adverse to including scrofula, dissenting in this from the usual opinion held upon the subject. Netter has charge of the chapters on acute pul-

monary and pleural diseases. André Petit has incorporated in his work on the heart all the various conclusions of Potain, Huchard, and others. The interdependence of the heart and its arterial ramifications are shown by these men to be clearly demonstrated by the pathological history of the circulatory system, hence we believe it would have been advisable not to subdivide the subject and not to assign the diseases of the blood-vessels to W. Œttinger. The latter writes also of acute articular rheumatism in a style that is neither masterly nor comprehensive. Why rheumatism should be classed, as it has been in this treatise, in direct sequence with aortic lesions, is a problem, for, although the circulatory disorders are only too manifest in rheumatism, it is at least supposable that vasomotor disturbances lie in a causal manner behind them, due most probably to a microbe yet to be found. The recent tendency is, as we know, to classify acute articular rheumatism among the infectious diseases.

A. Brault treats of the urinary diseases.

There is a slight divergence in the various treatments proposed for essentially similar conditions that leads one to hope that ultimately, in despite of old traditions, the doctor will have the courage to maintain an armed neutrality in all cases where an active interference is demonstrated to be of no avail. We refer for the moment to the revulsive treatment of exudations, which in pleurisy has been, according to Netter, so justly condemned by Wo'llez, Dieulafoy, Laborde, Germain Sée, and many others, but which, curiously enough, André Petit persists in recommending in pericarditis, at least as a means of relief to the patient. That André Petit can reason more wisely sometimes is well shown in his argument against Œrtel's treatment of fatty heart.

A Treatise on Nervous and Mental Diseases, for Students and Practitioners of Medicine. By Landon Carter Gray, M. D., Professor of Nervous and Mental Diseases in the New York Polyclinic; Visiting Physician to St. Mary's Hospital, etc. With One Hundred and Sixty-eight Illustrations. Philadelphia: Lea Brothers & Co., 1898. Pp. xi-17 to 687.

THE author states that the leisure of seven years was devoted to the preparation of this volume, and none but one of the foremost neurologists in this country could have succeeded in condensing within less than seven hundred pages a text-book on nervous and mental diseases. In fact, most writers on neurological topics have required that much or more space to present their ideas on either nervous or mental diseases alone. But the author's long experience as a teacher and his wide range of information regarding the literature of his subject have enabled him to discriminate nicely as to what knowledge is most needed by the student and practitioner. As he states, "superfluous knowledge, like surplus food, may clog the activity of the mind"; the researches of physiological chemistry regarding the autogenous intoxication products have demonstrated how surplus food may clog the activity of the mind, and a psychologist should be most alive to the disastrous results of mental cramming that tend to make the individual 'deep versed in books, but shallow in himself."

We wish that every medical college could have inscribed on its walls the following: "Medical nihilism is an error of youth and a confession of impotence, for Nature rarely afflicts man beyond the hope of relief. The therapeutist has enormous resources. Not only does the physical world provide a great variety of medicinal subjects and transmute its forces to suit his will, but likewise the physical world is bounteous in its aid. Far from spurning his inheritance, the ideal physician should gather his knowledge of disease and its antagonists from

every quarter, and exert every faculty for his patient's welfare, which is his own true success." Too often the instructor informs his pupils with exceeding care of the ætiology, pathology, and diagnosis of disease, and then says that it is incurable; he makes no effort to teach them what to do to alleviate, and Dr. Gray's optimism is in refreshing contrast to such instruction.

The first chapter reviews the anatomy of the brain, as on that foundation the superstructure of neurology is erected. The article is illustrated by well-selected engravings.

The second chapter is devoted to electricity. The author is in error in stating that the positive current flows from the positive plate and the negative current from the negative plate of the battery; the exact converse of this statement is the fact. We do not see why Figure 62 is reproduced as Figure 64 and also as Figure 79, especially as it is nothing but an illustration of a battery table.

The second part of the volume treats of nervous diseases proper. In the article on multiple neuritis we note a typographical error in the statement that Starr's Middleton Goldsmith (there spelled Middletown-Goldsmith) lectures were delivered in 1877; the date should be 1887. We think that there are recorded cases of beri-beri affecting Europeans.

Since the publication of the volume Zambaco Pasha's paper on Morvan's disease has been published. He visited Brittany, investigated Morvan's patients, and concluded that they were affected with anesthetic leprosy.

We are surprised to note the author's dictum that no case of hydrocephalus has ever been cured.

The author suggests that convulsive tic, or myriachit, be designated as palmus, derived from  $\pi a \lambda \mu \delta r$ , used by Aristotle to designate cardiac palpitation. Echolalie and coprolalie, used by the author, have been Anglicized in echolalia and coprolalia.

There are a few minor errors in the work that are comparatively unimportant and will doubtless receive attention in the next edition. We believe the volume will prove to be quite satisfactory for the purposes for which it is intended.

Holden's Manual of the Dissection of the Human Body. Edited by John Langton, Surgeon to and Lecturer on Anatomy at St. Bartholomew's Hospital, etc. Sixth edition. Revised by A. Hewson, M. D., Demonstrator of Anatomy, Jefferson Medical College, Philadelphia, etc. Three Hundred and Eleven Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1894. Pp. xx-25 to 803. [Price, \$3.]

This is an old friend in a new dress. Holden's Dissector has been known for many years as one of the best manuals for students' use, deservedly popular because of its pleasant style devoid of cumbrous detail and its simple diagrammatic illustrations. In the present edition many illustrations have been added and the text has been somewhat elaborated. While this results in an improvement in appearance, yet it would seem that in some cases the simple original plan has been lost sight of. Holden's design was not to write an elaborate descriptive anatomy, with artistic illustrations, but to make a book that should excel in simplicity and clearness and at the same time interest the student by a reference to practical points. Some of the older illustrations that are entirely inadequate to the present state of the science-such, for example, as the diagram of the course of the fibers through the medulla oblongata, on page 665-have been retained in the present edition.

The distinction between a dissector, a descriptive anatomy, and a topographical anatomy is not sufficiently borne in mind by those who prepare text-books. A dissector should be a technical manual describing the art of dissection and in-

structing the student in the preparation and dissociation of structures. It should stop there and leave the description of structures to the larger works, and introducing references to relations only in so far as is necessary to enable the student to understand his preparation. Excellent as this manual is, we believe that a book written with these facts in mind would fulfill all necessary functions in the dissecting room and yet be of not more than one fourth the size.

A Treatise on Ophthalmology for the General Practitioner. By Addit, M.D. Second Edition, revised and enlarged. With One Hundred and Forty Illustrations. St. Louis: J. H. Chambers & Co., 1893. Pp. xv-830. [Price, \$3.50.]

PROBABLY there is no subject in medicine with which the general practitioner is less familiar than with diseases of the eye. Few physicians have the time and opportunity to acquire a thorough knowledge of this specialty, but we believe that a careful reading of such a book as Dr. Alt has written would amply repay any medical man.

The general practitioner is forced to care for certain eye diseases even in large cities, and he should make himself thoroughly competent to treat such cases as do not demand a specialist's skill. Dr. Alt throughout the book has kept the needs of the general practitioner in view.

The directions for examination and manipulation are plain and precise. The diagnosis and treatment of the ordinary diseases of the eye and its appendages are thoroughly but concisely considered, while the complicated operations which only a specialist would undertake are very lightly touched upon.

The volume is written in excellent English and has a very pleasing appearance.

Manual of Bacteriology for Practitioners and Students, with Especial Reference to Practical Methods. By Dr. S. L. Schenk, Professor Extraordinary in the University of Vienna. Translated from the German (by the Author's permission) with an Appendix by W. R. Dawson, B. A., M. D., University of Dublin, etc. With One Hundred Illustrations partly colored. London and New York: Longmans, Green, & Co., 1893. Pp. xiv-310. [Price, \$3.]

In the first chapters of this volume the author describes the general morphology and biology of micro-organisms and the apparatus, reagents, nutrient materials, and methods necessary for their cultivation. A chapter is devoted to the microscopic examination of micro-organisms, the principal stains employed to color them, and the methods of determining their characteristics by means of experiments on living animals.

Then the author arranges his material in an excellent way, a chapter being devoted to the bacteriological examination respectively of air, of water, of earth, of food, and of purulent discharges, while four chapters are devoted to the bacteriological examination of the organs and cavities of the body and their contents. In an appendix inoculation against cholera, parasitic protozoa, the action of light on micro organisms, and some additional methods of technique are referred to.

The various details are described with sufficient fullness but without prolixity, and the book is one of the best working manuals for laboratory use that we have seen. The illustrations are excellent. On page 221 we notice that Pendjah ulcer is called Pende's ulcer.

A Clinical Text-book of Medical Diagnosis for Physicians and Students, based on the most Recent Methods of Examination. By OSWALD VIERORDT, M. D., Professor of Medicine at the University of Heidelberg, etc. Authorized Translation, with Additions. By Feancis H. Stuart, A. M., M. D., Member of the Medical Society of the County of Kings, New York. Third Revised Edition. With One Hundred and Seventy-eight Illustrations, many of which are in Colors. Philadelphia: W. B. Saunders, 1894. Pp. xv-700. [Price, \$4.]

The rapidity with which the second edition of this work has been exhausted, a third edition being demanded in less than two years, is evidence that the commendation that we bestowed upon it simply anticipated the professional favor with which it has been received.

The present does not practically differ from the preceding edition, and the translator and author have every reason to believe that the popularity of the volume will continue.

#### BOOKS, ETC., RECEIVED.

Operative Surgery. By Th. Kocher, M. D., Professor at the University and Director of the Surgical Clinic at the Berne University. With One Hundred and Sixty-three Illustrations. New York: William Wood & Co., 1894. Pp. ix-279.

Treatment of the Diseases of the Stomach and Intestines. By Dr. Albert Mathieu, Physician to the Paris Hospitals. New York: William Wood & Co., 1894. Pp. viii-294.

Holden's Manual of the Dissection of the Human Body. Edited by John Langton, Surgeon to and Lecturer on Anatomy at St. Bartholomew's Hospital, etc. Sixth edition. Revised by A. Hewson, M. D., Demonstrator of Anatomy, Jefferson Medical College, Philadelphia, etc. Three Hundred and Eleven Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1894. Pp. xx-25 to 803. [Price, \$3.]

The Physician's Wife and the Things that Pertain to her Life. By Ellen M. Firebaugh. Illustrated with Forty-four Photo-engravings of Sketches from Life. Philadelphia: The F. A. Davis Co., 1894. Pp. xi-186.

Notes on Nursing in Eye Diseases. By C. S. Jeaffreson, M. D., F. R. C. S. E., Senior Surgeon and Honorary House Governor to the Northumberland, Durham, and Newcastle Infirmary for Diseases of the Eye, etc. Bristol: John Wright & Co., 1894. Pp. vi-90. [Price, 2s. 6d.]

The Nurse's Dictionary of Medical Terms and Nursing Treatment. Compiled for the Use of Nurses, and containing Descriptions of the Principal Medical and Nursing Terms and Abbreviations, Instruments, Drugs, Diseases, Accidents, Treatments, Physiological Names, Operations, Foods, Appliances, etc., encountered in the Ward or Sick room. By Honnor Morten London: The Scientific Press, 1894. Pp. 139. [Price, 2s.]

Some Thoughts on Higher Medical Education and Medical Ethics. By David Cerns, M. D., Ph. D., Texas. [Reprinted from the Medico surgical Bulletin.]

A Case of Ringworm of the Scalp simulating Alopecia Aresta. By Henry H. Whitehouse, M.D. [Reprinted from the Journal of Cutaneous and Genito-urinary Diseases.]

The Absorption of Immature Cataract, with Restoration of Vision. By J. Hobart Egbert, M. D., Ph. D. [Reprinted from the Notes on New Remedies.]

Hernia and its Mechanical Treatment. By John B. Walker, M. D. [Reprinted from the Medical Record.]

The Diagnosis and Treatment of the Early Stages of Chronic Bright's Disease. By Boardman Reed, M.D., Atlantic City, N.J. [Reprinted from the Medical Record.]

The Direct Examination of the Female Bladder with Elevated Pelvis; the Catheterization of the Ureters under Direct Inspection, with and without Elevation of the Pelvis. By Howard Kelly, M. D. [Reprinted from the American Journ of Obstetrics.]

Electric Illumination of the Stomach. By Julius Friedenwald, A.B., M.D. [Reprinted from the Maryland Medical Journal.]

Migration of Syphilis from East Asia into America by Way of the Behring Sea. By Albert S. Ashmend, M. D., New York. [Reprinted from the Journal of the American Medical Association.]

Sur l'oblitération congénitale osseuse des choanes. Par A. Gouguenheim et L. Helary. [Extrait des Annales des maladies de l'oreille, du larynx, du nez et du phurynx.]

Report of the Eighth Annual Meeting of the Association of Executive Health Officers of Ontario, held at Gnelph, June 27 and 28, 1893. Also Index containing Lists of Officers and Contents of Annual Proceedings from 1887 to 1893.

The Demilt Dispensary in the City of New York. Forty-third Annual Report, etc., for the Year 1893, to which is appended Dispensaries, Historically and Locally Considered.

# Reports on the Progress of Medicine.

# ANATOMY.

BY MATTHIAS L. FOSTER, M. D., ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

The Influence of Function as Exemplified in the Morphology of the Lower Extremity of the Panjabi,-The influence exercised by pressure and posture in producing modifications of the skeleton is shown to a certain extent by Charles (Jour. of Anat. and Physiol., October, 1893) in an article with this title. He considers the changes brought about in certain bones of the lower extremity by the squatting posture generally assumed by the Oriental as compared with the form of the same bones in the European. The European sits upon a chair and can assume only at great inconvenience the squatting posture, which is not only customary to the Oriental, but one in which he can sleep as comfortably as in the supine. In this posture the back of the thigh rests upon the calf, the front of the tuber ischii being in close apposition with the heel, the hip, knee, and ankle being in extreme flexion, so the weight of the trunk is supported by the heels. The heels are apart about the distance that separates the ischial tuberosities, and the toes are turned outward. The Panjabi have an upright gait, though the tibia is very materially curved backward.

In the acetabulum the first and most distinctive difference is in the great size of the ischial portion of the facies lunata. The rim of the acetabulum here is very prominent, the groove for the obturator externus being consequently deep. Second, the extension forward and widening out of the lower horn of the facies lunata, whereby the cotyloid notch is, as it were, partly bridged over, instead of being an irregular open space. It looks as if the transverse ligament were ossified on its ischial side. Third, the cotyloid notch, which in the European is as a rule, open, is partially arched over by the forward and upward prolongation of the inferior cornu of the facies lunata. The superficial boundary of the cotyloid notch in the European consists of the transverse ligament alone; in the Panjabi it consists of bone plus the transverse ligament. The vessels en-1ering the joint pass under the bony roof, and not under the ligamentous portion.

The articular surface of the head of the Paojabi femur is of greater extent relatively and absolutely than that of a European bone. The articular area on the former is specially prolonged to adapt itself to the modified facies lunata of the acetabulum

during extreme flexion and partial abduction of the hip joint occurring in the squatting posture commonly assumed by the native of India.

The neck of the femur in the Panjabi is longer relatively than in the European.

The upper surface of the internal condyle of the Panjabi femur is partly articular.

The head of the tibia in the Panjabi is set on the shaft very obliquely. A Panjabi tibia can be held by the finger and thumb easily when the internal tuberosity is grasped behind by them

The upper surface of the internal tuberosity of the Panjabi tibia slopes considerably downward and inward; it is never flat-

The external tuberosity of the Panjabi tibia has its condylar surface convex from before backward, and the articular area is prolonged downward posteriorly.

The upper part of the tibial diaphysis in the Panjabi is commonly directed obliquely backward.

Flattening of the tibial shaft is fairly common. The individuals whose tibiæ were examined were neither hunters nor hill men, but dwellers in the plains. Any degree of platycnemia present could not, therefore, be due to the causes generally assigned.

A facet upon the anterior surface of the inferior extremity of the tibia was usually present for articulation with a like surface on the neck of the astragalus.

The facets upon the auterior inferior surface of the tibia and on the neck of the astragalus come into apposition during extreme flexion of the ankle joint in the squatting posture.

In more than seventeen per cent. of the tibis examined a second facet in a more internal position than the one mentioned on the anterior surface of the inferior extremity of the tibia was present and articulated with an anterior prolongation of the trochlear surface of the astragalus upon the upper portion of the neck of that bone. This facet has not been found when the external one was absent.

The Panjabi astragalus differs considerably from the European. There is a facet on the upper surface of the neck to the outer side and there is a facet on the same surface more internally, which is continuous posteriorly with the trochlea and internally with the pyriform malleolar articular area. This pyriform articular area on the inner surface is generally greatly prolonged forward, and, when that is the case, it is concave from before backward. The outer facet alone or the inner one alone may be present. The greatly elongated pyriform facet on the internal surface may be the only distinctive characteristic. The presence of the last-mentioned area renders the sartorial posture easier.

The resemblances between the osteological remains of the lower extremities of prehistoric man and those of savage or Oriental races of the present day may be due to the influence of common habits. It is highly probable that all the foregoing peculiarities are acquired; but that heredity has no influence has yet to be proved.

**Double Monstrosity.**—Windle (*ibid.*) summarizes his views thus:

- The cause of double monstrosity is a superfluity of germ plasm (determinants) existing in the germ.
- This superfluity of germ plasm leads in the case of true double monstrosity to a fission which is prior to that by which normal development is commenced.
  - 3. The superfluity may possibly be traced to-
- (a) The retention of superfluous germ plasm, owing to a faulty segmentation of the polar bodies.
- $(\delta)$  The introduction of superfluous germ plasm, from faulty segmentation in the formation of the spermatozooids.

- (c) The introduction of superfluous germ plasm by the entrance of more than one spermatozooid into the ovum.
- 4. The amount of duplicity depends upon the number of superfluous determinants retained in or introduced into the ovum.
- In homotopic redundancy the superfluous determinants follow the normal track in development; in heterotopic, an abnormal one.
- 6. It is possible that absence of normal determinants may coexist with the presence of abnormal ones in the same germ.
- 7. In the case of parasites, degeneration may be an additional factor in the production of the condition.
- Excess of growth without superfluity of parts depends upon different causes from those which produce double monstrosity.

A Left Vena Cava Inferior.—Waring (ibid.) gives the following description of a vena cava inferior found in a female subject in the practical anatomy room of St. Bartholomew's Hospital:

"The inferior vena cava is formed by the junction of the two common iliac veins in front of the middle of the body of the fifth lumbar vertebra and somewhat to its left side. The point of union lies directly behind the left common iliac artery and about an inch below the division of the abdominal aorta. The right common iliac vein is formed by the junction of the right internal and external iliac veins just external to the sacroiliac synchondrosis of that side. This vein lies behind the right internal iliac artery at its commencement, then to the inner side of the right common iliac artery, passing obliquely upward and across the right extremity of the sacral promontory to the lower part of the body of the fifth lumber vertebra, until it reaches the level of the middle of the body of this vertebra. At this point it passes to the left side of the middle line, lying behind the left common iliac artery and joining its fellow of the opposite side. The whole course of this vein measures two inches. The left common iliac vein commences behind the bifurcation of the left common iliac artery and in front of the left sacro-iliac synchondrosis by the union of the left internal and external iliac veins. The vein passes vertically upward, lying upon the left side of the body of the fifth lumbar vertebra. At its commencement it lies behind the artery, but in its course upward it immediately passes to its outer side, and when it is joined by the corresponding vein of the right side it is completely to the left of the artery.

"The inferior vena cava thus formed passes vertically upward for two inches. It is then joined on its left side by the left renal vein. In this part of its course it lies upon the fronts and left sides of the bodies of the fifth, fourth, and third lumbar vertebræ; to the right is the abdominal aorta, and to the left the left psoas muscle. Opposite the middle of the body of the third lumbar vertebra the left ovarian vein joins the inferior vena cava on its anterior surface.

"After receiving the left renal vein it passes obliquely across the anterior surface of the abdominal aorta to the right side of that vessel, and then lies upon the crus of the diaphragm. The oblique part, at its commencement, lies opposite the upper part of the third and the lower part of the second lumbar vertebrae. This oblique part measures an inch and a half in length. The right inferior angle of the oblique part is joined by the right renal vein, into which opens the right ovarian vein. Beyond this point the vena cava passes vertically upward to pass through the vena caval aperture in the diaphragm and join the right auricle. This portion measures three inches and a half in length. The other tributaries have their normal distribution, the azygos veins are normal, and there is no transposition of the viscera."

This unusual position of the vena cava Waring ascribes to faulty development. He adopts Hochstetter's view in regard to the development of the vena cava, and then explains the condition found as follows:

During development the lower abdominal portion of the right cardinal vein had either not been formed or had become obstructed. The pelvic communication between the posterior portion of the two cardinals had been established and persisted as the portion of the right common iliac vein which lies upon the body of the fifth lumbar vertebra. The left cardinal vein in the lower part of its extent had become much dilated, and formed the portion of the inferior vena cava below its junction with the left renal vein. The oblique portion which crosses over the anterior surface of the abdominal aorta had been developed from a dilatation of the anastomosis which is formed between the upper portion of the inferior vena cava and the left cardinal vein. The upper vertical portion had been formed by a dilatation of the small unpaired venous stem which appears in the tissue lying between the two primitive kidneys.

The Appendix of the Testicle.—Griffiths (ibid.) gives the following description of the little body situated on the upper and front part of the body of the testis, just in front of the globus major, which was first noted by Morgagni and is known as a hydatid. In the young it is a flat, tonguelike process, with a wrinkled or corrugated surface, hanging into the cavity of the tunica vaginalis, and having a flat, bandlike attachment at its base to the tunica albuginea of the testis, through which a few blood-vessels may be seen running into its substance. It measures from a sixth to a third of an inch or more in length. In the adult it may be of the same size as in the infant, or it may be so shrunken as to be hardly recognizable. It may be globular and firm, reduced to a mere stump, or altogether absent.

Microscopically, it consists of a process of fibrous connective tissue, which arises at right angles from the surface of the tunica albuginea and is directly continuous with the superficial layer of that tissue. In this connective tissue are many large blood-vessels proportionately to the structure itself. The surface of the appendix is wrinkled or thrown into irregular folds, and is covered by a single layer of subcolumnar cells, which rest on a basement membrane formed by condensation of the outermost layers of the connective tissue which constitute the substance of the body and are directly continuous with the flat endothelial cells lining the tunica vaginalis and covering the tunica albuginea, the transitional forms from the columnar to the flat variety being seen where the appendix joins the tunica albuginea. In no instance have any glandular tubules or any remains of true epithelial cells been found in the interior of this body.

In the adult the appendix is usually reduced in size, but may sometimes be found large and globular, owing to an increase of its fibrons connective tissue and the formation of cystic dilatations, which are dilatations of lymph spaces and not the result of distention of pre-existing gland tubules. The epithelium on its surface in all cases retains its subcolumnar shape, and shows no tendency to become flattened.

Cysts of the Epididymis.—The same author (ibid.) groups the cysts met with in the upper end of the epididymis under three headings—

- Small, pedunculated, and sessile cysts destitute of spermatozooids, so-called hydatids, which arise between the tubules.
- Single spermatozooid-containing cysts which arise from localized dilatations of the tubules.
- Multiple spermatozooid-containing cysts involving, as a rule, the tubules in one or more lobules (coni vasculosi).

The first class, small, clear, and translucent, are very frequently found in men beyond the age of forty years, occasionally in earlier life. They rarely exceed a quarter of an inch in diameter, though they may be of twice that size. Microscopically, they consist of a distinct cyst wall with an epithelial lining of non-ciliated columnar cells resting directly upon it. The cyst wall is composed of a thin layer of spindle cells resembling unstriped muscle fibers, together with a small amount of fibrous connective tissue. The fluid they contain is clear and watery, slightly albuminous, with numerous granules, a few cells with large nuclei, and granular protoplasm, but no spermatozooids. No connection can be traced between these cysts and the tubules of the epididymis beyond the fact that they take origin from among them. Griffiths considers that they originate as outgrowths or buds from the sides of the tubules, early lose their connection with the tubules, and so do not contain spermatic fluid, but simply a serous fluid, probably secreted by the columnar cells lining their walls.

The second class of cysts is not infrequently met with in men above forty years of age. They vary from a quarter of an inch to an inch in diameter, are in part imbedded in the substance of the epididymis, are composed of very thin walls, and contain a thin watery fluid in which numerous spermatozooids may be found, but usually only a small percentage of albumin. Lining the cyst wall is a single layer of non-ciliated, columnar epithelial cells, shorter and smaller than those lining a normal tubule. Sometimes such a cyst may be found with a thick wall and with the interior filled with a yellowish granular substance composed of cells, débris, and heads of spermatozooids. The structure of the walls of the cysts of this class, their epithelial lining, their situation, their contents, and the fact of their communication with the tubules of the epididymis, all appear in favor of the cysts being simply dilatations of the tubules in a given conus vasculosus. In short, they are retention cysts.

The third class, also found in men above forty, is cystic dilatation of a tubule in one or more of the lobules. These cysts are usually very small and numerous. The tubules, or portions of them, are dilated to several times their natural size, and as the dilatations increase they become more and more pressed together, and the intertubular connective tissue becomes less in amount, denser, and more fibrous. The wall of each cyst consists of a thin muscular coat, which is the flattened-out, thick muscular coat of the normal tubule. Each cyst is lined by a single layer of columnar, non-ciliated, epithelial cells, not so large as those found in the natural tubule. The cavity is occupied by numberless spermatozooids and a few large round cells.

Variations in the Position and Development of the Kidneys.—Brown (*ibid.*, January, 1894) classifies the abnormal conditions met with in the kidney under seven beadings:

- Kidneys normal in position and size, but altered in form.
   Kidneys normal in position, but altered in relative size.
- 3. Variations in number.
- 4. Variations in position-i.e., displacements.
- 5. Malformations.
- 6. Variations of the ureters.
- 7. Vascular abnormities.

Slight changes in form are not uncommon. The kidneys may be longer or broader than usual, sometimes approach the more globular feetal condition, and sometimes are discoid. Distinct lobulation is extremely rare.

The relative difference in the size of healthy kidneys is, he thinks, commoner than is generally supposed.

Absence of both kidneys must be exceedingly rare. Cases have been noted, but life must be impossible after a very few days. Cases of single kidney, by which the author means only

those in which one organ is congenitally and entirely absent, are also very rare. Alterations in form are not very common. The kidney rarely occupies an unusual position, though it has been found in the iliac fossa, and also higher and nearer the mesial plane than usual. The left kidney is more commonly absent than the right. In some cases no trace of a nreter corresponding to the missing kidney could be found; in others a rudimentary ureter was present. The adrenal body on the side upon which the kidney is present is usually normal in size and position; the position of the opposite one seems to vary somewhat, but it is practically always present, and lies usually in its normal position, though it may be somewhat altered in form. Congenital defects in other organs are exceedingly common. Beumer maintains that congenital defects and anomalies of the sexual organs ought to suggest the probability of congenital alterations of the kidneys. The absence of one kidney is found much more frequently in males than in females. As to the cause, the suggestion is made that the absence or small size of an artery at whose termination a viscus is developing or is about to form must play an enormously important rôle in the maldevelopment of that viscus. It does not seem to influence the duration of life, and is not unknown among the lower animals. Supernumerary glands-i.e, more kidneys than twohave been described in a few instances only. The supernumerary glands were then placed either near the two other kidneys or elsewhere in the abdomen or pelvis. Each one possessed a distinct ureter.

Displacements are much commoner than is usually believed. The author classifies them in three groups: Fixed displacements, where the mobility is always less than an inch in any direction; movable kidney, where the mobility exceeds an inch, where the organ is mobile in its relaxed adipose capsule or between the muscular wall of the abdomen and the peritonæum; and floating kidney, where the kidney has a mesonephron and floats in the peritoneal cavity. Slight displacements are very common. Dislocation is usually confined to one kidney, commonly the left. The displacement may be upward, so the organ may be higher than the spleen and push the diaphragm upward; it may be toward or from the mesial plane of the body, but usu ally it is downward, and the organ may lie in the iliac fossa, over the sacro-iliac joint, near the aortic bifurcation, or at or within the pelvic brim. It may be fixed beside the uterus, or lie between the rectum and bladder, and give rise to various troubles. A misplaced kidney has caused an obstacle to parturition, has been known to obstruct the bile ducts, and has simulated aneurysm. Movable kidney is commoner in women between twenty-five and forty years of age, and the right kidney is usually affected. Much has been said about its causation, but probably laxity of the abdominal walls and peritonæum is the most important factor. Floating kidney is very rare.

Fusion of the two kidneys the author classifies under malformations. All degrees of fusion have been found, from the horseshoe form to the most complete incorporation. The malformed double organ may lie in or near the mesial plane of the body, in the lower lumbar and iliac regions, or in the pelvis. The horseshoe form is the commonest, and occurs once in sixteen hundred cases. The other fusions are said to be present only once in ten thousand cases. In all forms two ureters are present.

It is fairly common to find the ureter on one or both sides double, but it always becomes single before it reaches the bladder. The extent of the doubling varies from a few inches to nearly its entire length. One case is recorded of a double pelvis and ureter.

The common irregularities in size, number, position, and source of the renal vessels have often been described.

Retained Testis .-- Griffiths (ibid.) concludes: 1. The retained testis in man and in the domesticated animals is of small size, and the seminal tubules, though smaller, are more distinct, owing to the disproportionate amount of intertubular connec-

2. The walls of the tubules are thick from the formation of fibrous tissue on the inner surface of the tunica propria; the epithelium is scanty and columnar, and there are no traces of spermatogenesis.

3. The testes in cryptorchids, though they are incapable of producing spermatozooids, are yet capable of exerting that influence which the natural testes exert upon the development of the penis and the growth of the body.

4. The function of the testes -namely, that which influences the growth of the body at puberty-is distinct from that of the production of spermatozooids, and the latter requires a more specialized development of the tubules of the gland than the

5. The testes do not acquire their full (spermatozooid-producing) function except at the farthermost point of descent from their primary position.

The Testes and Prostate Gland in Eunuchoid Persons.-The same author (ibid.) thus concludes a paper on this sub-

1. In eunuchoid persons the testes are of small size and al most entirely composed of fibrous tissue, the seminal tubules being represented by fibrous rods with fissurelike lumina containing atrophied epithelial cells. Although thus altered, the testes retain their normal shape and form.

2. The epididymides are large relatively to the bodies of the testes, and the tubules in most of the lobules of the globus major are natural, the tubules in some few lobules being altered as if by chronic inflammation.

3. The prostate gland is small, tough, and fibrous, and the glandular tubules are few in number and but imperfectly developed. The vesiculæ seminales are also of small size and devoid of any secretion in their interior.

4. Where the testes lose their power of growth, from whatever cause, the individual develops at puberty like a eunuch deprived of his testes in early life. Such a person the author, therefore, calls a eunuchoid.

Hermaphroditismus Transversus Virilis,-The same author, in the same paper, describes a very interesting case. The patient was twenty-three years old, and had never menstruated or had vicarious menstruation. The breasts and the mons Veneris were well developed. The vagina formed a blind sac two inches deep. The uterus was apparently represented by an elastic body of the size of a broad bean, lying rather to the right. In each labium majus there was an ovarylike body. These bodies were very tender and caused great pain; they were therefore removed. Careful examination showed that they contained tubuli seminiferi, and not Graafian follicles, and were distinctly testicles. There were vessels arranged like the spermatic and distinct cremasters, but no vasa deferentia. Perhaps, as Kochenburger suggests, they existed, but were cut too close at the operation to be recognized.

# Miscellany.

The Causation of Tetanus.—In the January number of

literature bearing upon the ætiology of tetanus, of their own previous articles on the subject, and of subsequent experiments which they have performed. They are led to the view that the micro-organism of tetanus acts not by its toxic properties, but by giving rise to a fermentation which engenders a toxic product. The article does not readily admit of condensation. The conclusions reached are thus expressed: 1. The bacillus of Nicolaïer engenders tetanus through the instrumentality of a soluble ferment which it gives rise to. 2. This ferment, which is not poisonous of itself, elaborates, at the expense of the organism, a substance which is directly tetanizing, producing effects comparable to those of strychnine. 3. This latter substance is found in abundance in the muscles of those affected with tetanus; it exists also in the blood and sometimes in the urine. 4. It resists prolonged boiling, but the bacillary products are rendered inert by heating to 149° F. 5. It requires for its formation favorable conditions of temperature. Thus is explained the immunity of the frog in winter. 6. Natural or acquired immunity may be considered as the result of causes which prevent, retard, or arrest the fermentation above referred to. 7. It is probable that other microbian substances called toxic likewise act as soluble ferments to produce toxic substances at the expense of the organism.

Fevers without Fever .- Such attacks, says a correspondent of the Journal des praticiens for February 7th, have been noticed before now, especially in scarlet fever, malarial seizures, and typhoid fever, running their course with a subnormal temperature. Influenza presents this abnormal occurrence, as M. Teissier, of Lyons, has often proved. He it is who has now drawn the attention of one of the societies to pneumonia running its course without fever. A patient in his service at the Hôtel Dieu complained of all the symptoms of pneumonia, but the temperature remained low, almost subnormal, and did not begin to rise until about the sixth day-i, e., at the time when the convalescence began. From this time on the thermometer remained above normal. This is the course of temperature which M. Potain has noticed in an apyretic form of typhoid fever. To interpret facts of this sort, it has been imagined that there might be secreted by the germs pathogenic products that were sometimes pyretogenous and sometimes refrigerant, and in support of this idea reference has been made to Roux's and Pittion's experiments in injecting the urine of influenza patients into animals, those of Rodet and Coumont with the products of the staphylococcus, and those of Charrin. Gilbert, and Boix with those of the Bacillus coli and of Eberth's microbe. Such an explanation is not wholly satisfactory to M. Teissier. He thinks it more probable that this reduction of temperature is due to the retention of products of cellular nutrition under the influence of the action exerted by the infectious germs. He compares these occurrences to those which rheumatic and gouty persons experience after overeating or exposure to cold and dampness (lassitude, local congestions, and heat of the skin, but with a reduction of the temperature below normal). A practical remark remains to be made. In these cases M. Teissier employs quinine, and that drug raises the temperature. This has the appearance of a paradox, since no reason can be given for it, but it is none the less real and practically useful. At all events, adds the correspondent, clinicians can not be too much encouraged to give attention, as M. Teissier has done, to instances of the sort.

A Fatal Case of Acute Parenchymatous Nephritis Consequent on Impetigo. - In the February number of the Revue mensuelle des maladies de l'enfance there is an abstract of an the Revue de médecine M. J. Courmont and M. M. Doyon give a account of such a case, by Dr. Pietro Celoni, published in the review of the most important of the recent contributions to the Archivio di pediatria for July, 1893. It appears that several cases of nephritis consequent upon eczematous or impetiginous eruptions have been observed by the Italian physicians. Guaita, Canali, Felici, and Rigoli have published pretty conclusive examples of inflammatory affections of the kidneys consecutive to more or less extensive cutaneous diseases. Some see only a coincidence between the nephritis and the skin disease; others take the former as dependent on the latter, and think that the agents which give rise to the nephritis must have penetrated through solutions of continuity of the skin. The particular case related by Celoni was that of a boy five years and a half old. It ran its course in four days and ended in death with all the symptoms of acute parenchymatous nephritis. The child had been attacked with impetigo three weeks before. The bacteriological examination was negative, so the case is not wholly cleared up.

The Medical Society of the State of Pennsylvania,-

At its last meeting the society appointed—under the provisions

of a by-law proposed at Harrisburg and adopted at Williams-

port-a committee on scientific business, "to secure scientific papers and to provide scientific discussions for each annual meeting, and to co-operate with the committee of arrangements and credentials in arranging the programme." The members of this committee are Dr. Dulles, of Philadelphia; Dr. Gorgas, of Harrisburg; Dr. Le Moyne, of Pittsburgh; Dr. Tyson, of Philadelphia; and Dr. Towler, of Marienville. The object of this change in the law is to have a permanent committee which, becoming familiar with the subject, shall find it easier to secure good scientific work than is possible for a committee that is appointed new every year. The committee on scientific business is working in conjunction with the committee of arrangements, of which Dr. E. E. Montgomery is chairman, and will co-operate with it in arranging the programme. The committee, in a circular dated February 15th, expresses the hope that each member of the society will aid it in attempting to make the meetings of greater scientific importance than they have been in the past. To this end the committee will welcome suggestions from any member of the society and espe-

cially, at this time, offers of contributions to the work of the

next meeting, at Gettysburg, May 15th to 18th. It is desired

that there should be as many brief, concise, practical papers as

possible, and it is proposed to have a discussion on tuberculosis,

devoting the morning to medical tuberculosis and the after-

noon to surgical tuberculosis. Any communication from mem-

bers of the society in regard to the work of the committee will

be welcomed by it. Members of the society desiring to read

papers or to take part in the discussion on tuberculosis are

asked to notify the chairman of the committee, Dr. Charles W.

Dulles, 4101 Walnut Street, Philadelphia.

The New York Academy of Medicine.—The special order for the meeting of Thursday evening, the 1st inst., was a paper by Dr. A. M. Phelps, entitled Pott's Disease of the Spine; its Early Symptoms and Diagnosis; Spinal Supports, their History and Growth; Treatment, Surgical and Medical.

At the next meeting of the Section in Public Health, Legal Medicine, and Vital Statistics, on Wednesday evening, the 7th inst., Aaron M. Powell, Esq., will read a paper entitled The Question of State Regulation of Prostitution.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 8th inst., papers on Bronchitis in Infants and Children will be read by Dr. A. Reich, Dr. Charles G. Kerly, and Dr. Henry Koplik.

At the next meeting of the Section in General Surgery, on Monday evening, the 12th inst., Dr. C. N. Dowd will read a paper entitled Considerations on Different Types of Surgical Inflammation, based on Bacterial Examinations in 125 Cases;

and Dr. Willy Meyer will read one on Practical and Efficient Sterilization of Materials for Private Operations.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 13th inst., a paper on Posterior Urethritis will be read by Dr. F. Tilden Brown, and one on Periurethral Phlegmon near the Frenum by Dr. R. Guiterns.

The External Use of Guaiacol,-In the Province médicale for February 3d there is an article on this subject of which the following is the substance: This procedure, which was used by Sciolla and Bard, has for some time been employed as an antithermic. It consists in painting the greater part of the exterior wall of the thorax, and sometimes the forearms, with pure guaiacol. According to different authors, the doses are variable, ranging from one or two cubic centimetres up to seven or eight. There is a difference of opinion as to the employment of this liquid. Sciolla, Bard, and other physicians use pure guaiacol, while others, like Desplats, mix it with glycerin or alcohol. In several case of advanced phthisis, a marked reduction of 2° has been obtained by painting the entire surface of the front of the thorax with pure guaiacol. Unfortunately, the effects of this treatment are only temporary, not lasting more than three or four days. Sometimes, also, applications of this kind produce a marked rise in temperature-in one case of 2°. It is necessary, then, in making use of this procedure to ascertain the susceptibility of the patient, and to use at first small and then progressively large doses. There have been of late years interesting attempts in the employment of this procedure. Casasovici and Miron Sigalea have used guaiacol mixed with tincture of iodine, in the treatment of pleurisy, in the following proportion: Tincture of iodine, three hundred and eighty-five grains; guaiacol, seventy-five grains. This quantity is used in a single application, and the diseased parts are thoroughly and extensively painted with it every night. These applications cause a considerable reduction of temperature, profuse perspiration, and an increased flow of urine, followed soon after by complete resorption. These results seem to have been obtained, particularly in one case, where there was abundant pleuritic effusion on the left side, in which tapping had not been followed by any relief, but had caused a considerable rise in temperature, by the application of iodized guaiacol, the fever disappearing in a few days and the effusion becoming resorbed.

M. Desplats has recently conceived the idea of applying guaiacol in the treatment of painful rheumatic inflammation of the joints, after having observed a case in which applications of guaiacol had been used with excellent results. He has used a mixture of equal parts of guaiacol and pure glycerin. The joints were thoroughly painted with this mixture and afterward covered with a dry dressing. In one case of acute rheumatism and in three others of arthritis deformans with sharp pains, the results were excellent. The pain was completely subdued, and in the first case the patient recovered rapidly. This procedure has recently been employed in applying guaiacol for articular neuralgia of the shoulder, which was very painful, in a tuberculous patient, who experienced marked relief. It is easily employed and not dangerous if the indications mentioned are conformed

The Dose of Atropine.—The Journal de clinique et de thérapeutique infantiles remarks that atropine should not be used internally in children under fifteen months old. Of a 1-to-1,000 solution of the sulphate in distilled water, from two to five drops may be given in the course of twenty-four hours to a child between fifteen months and three years old, from five to ten drops to a child between three and five years old, and from ten to twenty drops to one between five and ten or twelve years old.

# THE NEW YORK MEDICAL JOURNAL, MARCH 10, 1894.

# Rectures and Addresses.

# MODERN EXPERIMENTAL MEDICINE.

ANNIVERSARY DISCOURSE, NEW YORK ACADEMY OF MEDICINE, November 29, 1893.

BY WILLIAM H. THOMSON, M. D., LL. D., PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS AND OF DISEASES OF THE NERVOUS SYSTEM, UNIVERSITY OF THE CITY OF NEW YORK.

Mr. President, Fellows of the Academy, Ladies and GENTLEMEN: No physician who has lived long enough in the practice of his profession to compare the state of medical knowledge and of opinion as it was twenty-five years ago with the same at the present day can fail to recognize the fact that in both a virtual revolution has characterized the interval. This change is not simply from increase of knowledge, great as that has been, but more from change of methods in the pursuit of knowledge, with the result of altering the whole domain of medicine to an extent which only the term revolution can fully express. It happens, however, that, as in other revolutions, many who live in their epochs, and who even may take part in them, yet fail to appreciate at the time their full significance, and therefore remain long unaware of the essential difference which separates the new order of things from the old. With a view, therefore, to illustrate the import of the new era which is now fully upon us, I would briefly refer to the chief methods of inquiry and of investigation which were pursued by the medical profession a quarter of a century ago, and then compare them with the experimental medicine of to-day.

First of all in the estimation of the profession at that time came clinical medicine, or the knowledge that could be gained of disease at the bedside of the sick. To be able to investigate disease to good purpose when face to face with it required no small preparation on the part of the physician. For that preparation anatomy was the first lesson, and no complaint can be made that this essential prerequisite to any true medical science was then, or ever has been, underestimated. No sooner, in fact, was the microscope put within reach than everywhere workers set themselves to extend our knowledge of the structure of living tissue, until the vast field of histology, or the ultimate anatomy, as it may be termed, was explored in every direction, with the most fruitful results, though thereby more than doubling the amount of study now required for even ordinary medical equipment, compared with that of previous generations. With each advance in knowledge of structure it was to be expected that similar gains would be made in knowledge of function or working, and physiology accordingly kept even pace with anatomy both in the extent and suggestiveness of its discoveries. But life has also its own chemistry, and no charge can be made against the profession that it failed to recognize the importance of that great science in its relations to health and to disease.

With as perfect qualification in these respects as the

works treating of their general and of their specific forms, or their natural history, so to speak, as revealed in their symptoms, course, and terminations. Finally, to complete this came the great science of pathological anatomy. From ancient times it has been felt that death by disease had many explanations to offer for itself in the records which it leaves of its ravages in the body, and no one can speak too highly of the patience and skill with which unnumbered scientific men in our profession have labored to trace the minutest steps of deviation from healthy structure which the post-mortem table can reveal, and to determine their relation to morbid processes before death.

With all these requisites mastered, clinical observation began. For this also a special training was needful. After an inquiry into the history of the patient, involving often a cross-examination as special in its way as that of a skillful lawyer, though as far as possible from a lawyer's usual intentions, the clinician begins to observe for himself. The great physicians of antiquity admirably had paved the way by showing how much the eye alone could note in disease, and it would be well for us in this generation to go back to those old masters for many a now too often neglected lesson. But modern research has added the accurate sense of hearing in the methods of percussion and auscultation, and refined many of the applications of the sense of touch, and finally called in the invaluable aid of chemistry and of the microscope for the examination of the secretions-all to guide the medical man up to the point when he will show what his own mind is capable of toward correctly estimating the relative importance of each, among often a wonderful complex of details.

Now why is all this not enough? Why is this trained investigation of disease, with all its helps for the interpretation of its manifestations or of its issues, whether in recovery or in the anatomical changes shown by autopsies, not sufficient to advance medical knowledge until every serious problem of medicine be solved ? The answer is that by none of these methods can the vital question of ætiology, or the causation of disease, be answered with anything like a satisfactory demonstration, owing to the absence of one great requisite in all scientific demonstration-namely, experiment. In no scientifically conducted investigation is observation alone sufficient. Observation never can be safely interpreted except by testing. All interpretations of observations remain mere theories until they are experimentally tested. But observing over and over again is not testing; it still remains observing. How deficient, therefore, both clinical medicine and pathological anatomy may be in securing the final interpretation of disease one example will suffice to illustrate:

No malady has been more thoroughly studied, either at the bedside or post mortem, than pulmonary consumption. Both its distressing clinical features and its fearful mortality furnished the strongest incentives for its exhaustive investigation, while its chronic course gave ample time to note everything connected with its development. For centuries, therefore, it has been closely watched, till not one student could obtain, diseases then came to be studied in of the minutiæ of its characteristics escaped observation.

But to what conclusive results did all this clinical and anatomical study attain? Not to go back too far, I remember a sagacious and acute observer among my teachers eloquently advocate the view of his great teacher, Laennec, that tuberculosis was a constitutional tissue degeneration, so hereditary, therefore, that, as my professor expressed it, it began in the ovary of the mother. But whereas Laennec said in 1819, and said rightly, that the existence of tubercles in the lungs is the cause, and constitutes the true anatomical character of consumption, the eminent German teacher, Niemeyer, in 1867, said wrongly that tubercles had no causative connection with phthisis, and when found in the lungs after death they were inflammatory products of recent origin which only complicated the disease after it was already in an advanced stage. Louis, the successor of Laennec, and his followers taught that the yellow or cheesy masses of degenerated tubercles were the true tubercles, and were deposited as such from the blood. Virchow, on the other hand, came near denying that cheesy deposits in consumptive lungs had anything to do with tubercle.

Now, no one can allege that these distinguished men whom we have mentioned were either incompetent clinicians or pathologists. Can any better than they be expected in the future? If not, then how long would the profession have had to wait for a final agreement among such authorities on this subject? From what has developed since, the answer would be, Forever. Far as clinical observation can go, it could never have shown the cause of consumption on a wall, or have forbidden floor sweeping on account of it; and as to pathological anatomy, while we think Sir Andrew Clark's remark much too sweeping which he makes in his last published lecture on fibroid phthisisviz., that "the anatomical structure of a morbid product can never be made the true criterion of the disease which produces it"-yet pathological anatomy had been given as full time and opportunity as clinical observation to discover the true ætiology of phthisis and had equally failed.

The first real advance toward the solution of the problem was made, as is well known, by Villemin in 1865, when he startled the medical world by announcing what was really a confirmation of a forgotten experiment made as far back as 1843-viz., that tuberculosis could be caused in perfectly healthy animals by inoculating them with tuberculous matter from persons sick with consumption. Experimenters in all countries speedily confirmed this epochmaking discovery. But upon this followed a crowd of most puzzling reports of experiments, which, however, most instructively illustrate the intrinsic excellence in the long run of the experimental method, for at first it seemed as if the experimental investigation of the nature of tuberculosis was going to lead to greater confusion than ever. Dr. Burdon Sanderson found that he could produce tuberculosis in animals by inoculating them with pus taken from pyæmic patients, or even after the mere introduction of a clean seton of unbleached cotton. Dr. Wilson Fox did the same in guinea-pigs by inoculating them with vaccine lymph. In Germany, Cohnheim and Fraenkel also succeeded in producing tuberculosis by introducing all sorts of things, from pieces of healthy muscles to bits of charpie or gutta-percha. The the disease in question.

inference, therefore, seemed justifiable that anything which artificially produced an inflammation could give rise to tuberculosis, much to the delight of Niemeyer. Ere long, however, it was discovered that it altogether depended upon where the animals were at the moment they were experimented upon whether they became tuberculous or not. If they were taken out of cages or rooms in which other animals had died of tuberculosis and were then wounded, especially with instruments which had been used on tuberculous subjects, they contracted tuberculosis, no matter what was used. But if precautions were taken against any contamination of the kind with tuberculous matter, then they never became tuberculous until they were inoculated with actually tuberculous material. On the announcement of this fact by Klebs, one by one of the other experimenters mentioned repeated their experiments and finally acknowledged that Klebs was right, until a general agreement was reached, as demonstrated by experiment, that tuberculosis is a specific infectious disease which never occurs in an animal body except it comes from a previous case of tuber-

We have said that this history illustrates the intrinsic excellence of the experimental method, for while at first, in this instance, it scarcely seemed to settle anything, it finally did settle what it set out to do conclusively. This the experimental method does by providing by its own laws for the correction of its own mistakes. Mistaken experiments, unlike mistaken doctrines, are always short-lived, and we commend this fact to all those who dwell upon the contradictory reports of experimental investigation in many questions now before the medical world, as if certainty can never be thus reached. From its very nature, the experimental method gets at its hid treasures by no lucky find in the field, but only by the slow approaches and perfecting which mark every human invention, taught often as much by failure as by partial success, and content with nothing short of complete solution. The reason of this last characteristic is that the solution is never left to one person or judge. Every claim of the kind is passed upon by a very large jury of experimenters in all civilized countries, each one of whom tests the solution by experimenting upon it himself. Only what is true, therefore, can survive such an ordeal.

But to return to tuberculosis. Experimental medicine could not stop with the confirmation of Villemin's discovery. One discovery made, urgently called for a further discovery. As tuberculosis is an infectious disease, what is the infecting agent? Among the many who set themselves to answer this question, it fell to Robert Koch to make the identification, by the strictest rules of experimental investigation, which, as he formulated them at this crisis in his own personal history, illustrate the noble quality of scientific conscience quite as strikingly as his work did that of scientific skill. No investigator, he said, can profess to have demonstrated the causative connection between an observed element in a disease, when it is a microorganism, and the disease itself—

 Unless the micro-organism is present in all cases of the disease in question.

- 2. It must be present in this disease and in no other.
- 3. It must be found in such quantities in the infected body that all the symptoms of the disease may be clearly attributable to it.
- 4. It must be capable of isolation from the infected body and of being separately cultivated where it can not be confounded with any other micro-organism.
- 5. These artificially-grown colonies must then be capable of reproducing themselves in animal bodies after inoculation with them.
- 6. They should then cause just the same disease in symptoms and in anatomical changes as the original

Now, these rules plainly imply that all experimental investigation into the facts of life and of disease is beset with fallacies-fallacies partly inevitable, and partly due to the natural eagerness of inquirers to make striking discoveries. But by such rules an effective check is imposed from the first upon any straying from the path of testing and of retesting. The experimenter has to stop and wait for five other corroborations of his first experiment ere he can certify demonstration. Then at every step he must report, not his views or his conclusions, but instead fully detail his methods of working. Room for views or opinions there is little or none. From first to last nothing is considered but questions of fact.

It is well that this should be so, for when these demonstrated facts were first reported about tuberculosis, owing to their extraordinary and well-nigh unimaginable character, they would have met with nothing but general incredulity were it not that all evidence, when it is fully certified by experiment, is simply resistless. A lung stuffed with tubercles must swarm indeed with Koch's bacilli when, according to Bujwid's estimate, 5,000,000,000 of them can enter a drop of water. Still, minute as they are, they are not dissolved in it, for they can all be filtered out of it as so many solid particles. Moreover, a whole series of facts have been further demonstrated about them which it is of supreme importance for us to know. First, they are living things, with as definite a life history as other living things. They can be cultivated in or on different media outside of the body, and generation after generation of them can so be raised, with full opportunities thus given for watching all their facts of growth. Koch still keeps propagating in his laboratory cultures descended from the first which he planted in 1881, just as a farmer might do with his different kinds of grains and thus know the difference between them when grown on this soil or on that. Thus it seems that the range of temperature under which they will grow is more restricted than with other micro-organisms—37° to 39° C. being the best. Nevertheless, they are not killed by freezing any more than winter-sown wheat. On the other hand, whereas the cholera bacilli are quickly destroyed by drying, tubercle bacilli will retain their vitality in dried sputum for nine to ten months; hence the deadly peril from the dust of rooms in which consumptives have carelessly expectorated. Moreover, these bacilli have great powers of resistance against certain germicides which are promptly fatal to other bacteria. They are not destroyed by the We may here quote the rather extreme views of Mr. Victor

gastric juice, and hence, when taken in meat or milk, will pass on to invade the system through the abdominal walls. Nevertheless, they are extremely susceptible to direct sunlight, which kills them in a few minutes, and even in the diffused light of a room with good windows they will die in six to seven days. We need not fear, therefore, the consumptive's expectorating on the sidewalk, however careful we should be about him indoors.

Already, therefore, we are in possession of such priceless information as this: First, that this fell destroyer of the human race is a preventable disease, and therefore we may confidently look forward to the time when, instead of its being one of the commonest causes of death, it will become as rare as leprosy is now. Even now, through the exertions of Koch, Cornet, and others, the German public is becoming aware of the need of disinfecting, as they recommend, all articles likely to be contaminated by phthisical patients, and already, according to Dr. Woodhead, there has been a diminution in the deaths from phthisis in the Grand Duchy of Baden from 3.08 in 1,000 in 1882 to 2.80 in 1,000 in 1887, a percentage of decline which Dr. Woodhead estimates would, in the British Isles, amount to a saving of nearly 10,000 lives per annum.

The second great fact is that, though tuberculosis is as communicable a disease as small-pox is, in that it never occurs except as it has been communicated from one sickened by it, yet, wholly unlike small-pox, it is not a contagious disease—that is, it is not communicated by mere proximity to a consumptive. It would be cruel, therefore, to treat consumptives as we must for our safety treat small-pox cases. Instead, experimental medicine tells us just what we are to do to arrest this infection-where we are to find it so as to destroy it after it has left the body of the consumptive-and if the medical science of our day had only done that it would still deserve the gratitude of all man-

We now come to the requisites for prosecuting the researches of modern experimental medicine. It will be seen that they imply the formation of a large body of investigators, operating on quite distinct lines of experimental inquiry, and yet each branch of the service indispensable sooner or later to the others.

First in order is the worker in the physiological laboratory. Without his researches into the laws or mechanism of motion, sensation, respiration, circulation, secretion, nutrition, reproduction, and other living functions, many deductions of the other workers might be dubious till his verdict was rendered. For example, a very important question is now raised whether cancer is a parasitic disease like tuberculosis, because some epithelial cells in cancerous tumors are found with suspicious looking cells inside of them. Are these latter parasitic invading cells, or do epithelial cells sometimes naturally-that is, physiologicallygive birth to cells within them, or endogenously, as it is termed ? It is obvious that that question must first be answered from the physiological laboratory ere the original question can go further.

Next comes the laboratory of experimental pathology.

Horsley, in his address as president of the Section in Pathology of the British Medical Association at its meeting in 1892, of what relation experimental pathology has to pathology itself. He says: "However absurd the statement may appear to some, I venture to assert that pathology as such is almost unknown among us [in Britain]. The fact is that what is commonly spoken of as 'pathology,' taught as 'pathology,' and made the subject of examinations in 'pathology,' is nothing of the sort; it is not pathology; it is morbid anatomy. . . . We have in London a society whose function, as defined in its title, is to promote the study of pathology, but, unfortunately, it has hitherto been only an emporium of morbid anatomy. Thus, even when during the last two years as many as three hundred and twenty papers were communicated to the Pathological Society, not ten, and in 1890 not a single one, dealt primarily with the pathology of any disease. . . . The pathologist should be the student of disordered function as well as of disarranged structure; morbid anatomy is therefore but one side of his work, pathology is the other. As, however, so far as I am informed, there are only three places in England where pathology is taught, the paucity of true pathological research among us can not be regarded as a matter of surprise. It does not seem to be generally appreciated that what is required at the present day is the accurate determination of the observations of normal function, and, seeing what strides normal physiology as a science has made, no difficulty attends the pathologist in this new and fertile field."

Referring to a celebrated discussion on the origin of the dropsy in Bright's disease, which occupied several sittings of the London Pathological Society, and which was participated in by a number of the most distinguished physicians of that capital, he says: "Even in this very year, in a great discussion on the cause of dropsy, and one which appeared to many to be fruitful in little but surmises, opinions that dropsy is due to alterations in the blood pressure alone and chiefly to venous stagnation were freely promulgated and confidently relied upon. Yet they have for more than twenty years been absolutely contradicted by experimental pathologists, and shown to be untenable. I have not the slightest hesitation in saying that this surprising ignorance of pathology is due to want of familiarity with modern progress in physiological and chemical research. Fortunately, laboratories are springing up now on all sides, original investigations are being pushed forward, and the reproach that we have been dead-house students rather than true pathologists will therefore soon be wiped away."

Mr. Horsley speaks rather warmly, being an experimental pathologist himself. His experiments on the artificial production of myxedema in dogs by the extirpation of the thyreoid gland led directly to the recent remarkable results in the treatment of that hitherto most serious disease in the human subject by the administration of thyreoid extracts, thus opening an entirely new field in therapeutics, the full extent of which can not at present be estimated. But if, from various causes, there have been till lately in England but few laboratories for studying morbid processes in the same way that the physiologist investigates healthy

processes, the reverse is the case in other European countries, where such laboratories are attached to nearly every university and leading hospital.

Next in order comes the bacteriological laboratory. This generation will ever be known in medicine as the bacteriological era. The wonderful results in the saving of life by arresting the terrible scourge of puerperal fever, by enabling surgery to reduce the mortality from accidents or operations to a degree undreamed of twenty-five years ago. and the power which our profession now has to stop the march of the great Asiatic epidemic more effectively than any army has ever defended its country from an invader, have already familiarized the general public with the fact that a greater discovery has been made in this generation than the discovery of the uses of steam or of electricity. That discovery is the relation of the unseen earthly world of life to the seen. In actual bulk the living kingdom invisible to the naked eye is greater than the visible, because it is relatively omnipresent, while the visible is relatively local. But just as the visible vegetable and animal kingdoms are vitally interdependent, so this great discovery reveals the fact that, but for the invisible kingdom, the visible could not long continue to exist, for Nature soon would be choked with her own dead. It is to the activity of the world of microorganisms that whatever has ceased to live is dissolved away into its original elements. The general relation of micro-organisms, therefore, to the other departments of life is beneficial and necessary. But it happens that there are some members of this vast host which can work mischief in animal bodies before death, each in its own way, and thus become directly causes of specific diseases. But how separately to identify any particular form among so many millions, and fasten upon it the indictment of a disease producer, is a much more difficult task than to single out one ruffian from the midst of a surging crowd of Gravesend voters and then prove the case against him. How deftly this has to be done in the case of bacteria, where so many look much alike, without having other bacteria confuse the verdict by crowding in along with the suspect, is illustrated by [any] one of the procedures recommended for getting a pure—that is, an unmixed—culture of the tubercle bacillus. As it is difficult to obtain pure cultures from tuberculous sputum, on account of the presence, just mentioned, of other bacteria, which grow much more rapidly and take full possession of the culture plate before the tubercle bacilli have had time to form their colonies, it is best first to inoculate a guinea-pig with the sputum from a consumptive, and to obtain cultures from it after the infection has become fully developed in it, which usually takes about three weeks. The guinea-pig should then be killed in a room wholly free from dust and its body laid on its back on a sterilized board, after its skin has been thoroughly washed in a 1-to-1,000 solution of corrosive sublimate. Then, having sterilized beforehand a number of knives, scissors, and forceps by passing them through a flame and quickly putting them under a glass bell jar till they are used, the operator, having already thoroughly sterilized his own hands, cuts the skin over the thorax and turns it back only just enough for his purpose. Fresh instruments are then taken to avoid pollution by stray germs, an opening is made into the chest cavity, the root of the lung drawn out, and a well-defined tubercle nodule is taken out with a slender, sterilized forceps and the nodule transferred to a sterilized glass dish. Time obliges me to leave the next details how to inoculate the culture medium, except to say that finally, to keep the said medium from becoming too dry for the development of the bacillus, it is best to keep the cultures in a moist atmosphere, and to prevent evaporation by a rubber cap over the end of the test tube, which cap should be sterilized in a 1-to-1,000 solution of sublimate for destroying the spores of mold fungi, which in a dry atmosphere would be harmless, but under the rubber cap are likely to sprout and send their mycelium through the cotton plug to the interior of the tube, thus destroying the culture.

We have quoted all this merely to give some idea to those unfamiliar with the subject that the modern germ theory of disease is not built on theorizing, but, instead, on extremely careful work. Then it is but the beginning of this work to observe the forms or appearances of the microbes, though, to do that properly under the microscope, bacteria have to be stained with certain dyes, then washed in water or alcohol; then these dyes are in turn partially decolorized by chemical agents and then dyed again, each among a multitude of species often demanding a complicated formula of its own for the process. But, as we have said, after all this, further researches are needed to prove that this particular one is the sought-for kind, because other and very different bacteria may show the same appearance which it does. Thus, after Koch identified the comma bacillus of Asiatic cholera, it was soon alleged that a similar comma bacillus could be obtained from the dejecta of persons sick with ordinary cholera morbus; and then another comma bacillus, still more resembling Koch's, was reported as growing in old cheese. Pickpockets in a crowd may be suspected on account of their looks, but only their behavior justifies their arrest, and likewise it is necessary to observe the behavior of bacteria much more than their looks. This can be done only by finding suitable media outside the body in which they will grow. Growing microbes, however, is a very special business. In an ordinary garden it needs much industry to keep weeds out of particular beds, but how to keep microbe weeds out of a prepared culture medium often taxes the patience and skill of the bacteriologist beyond description. For a long time the whole investigation was retarded by difficulties of this kind when they were first cultivated in nutrient liquids, and it is one of the great services of Koch that he devised the method of cultivating on solid nutrient surfaces, such as gelatin, agar jelly, etc.

With a final success in obtaining a pure, or unmixed, culture, the task begins of observing how they develop, what makes them grow freely, and what checks them, for only thus can be learned the most certain methods of destroying them—that is, of securing disinfection. But this valing bacteria are met by hosts of the white corpuscles of entails more painstaking watchfulness than is demanded of any other cultivator, for often more is learned from the chemical effects of the growth upon its medium or soil than from any other results of the whole process. Hence

it is easy to see that this branch of experimental medicine demands a precision in work which implies in the investigator not only a thorough training in microscopy and in chemistry, but also the possession of appliances and contrivances which make a modern bacteriological laboratory one of the most striking monuments of science which the world has ever seen.

Lastly, chemistry is indispensable to experimental medicine. This majestic science, whose field is conterminous with the material universe, in none of its branches is more important or more recondite than in the chemistry of life. It is now clearly recognized that without chemistry, bacteriology would help us but imperfectly in the problems of infection. The earlier view, that bacteria work their mischiefs by themselves invading the blood or the tissues, and that they are to be discovered there, is now much modified by the knowledge that the action of many of the disease producers is by their forming virulent chemical poisons which are absorbed into the circulation from local seats of bacterial growth. The microbes which do the deadly work of diphtheria do it all where they form the diphtheritic membrane, for as they grow there they generate three different chemical poisons which are absorbed into the blood and which have been isolated in chemical laboratories where such investigations are carried on, and which poisons injected into animals produce just the fatal paralyses, the fatty degeneration of the heart, and the general systemic changes which are found in human victims of this disease. The bacillus of typhoid fever and the microorganism of Asiatic cholera both live in the intestine and there generate the poisons, which, absorbed into the blood, give rise to the symptoms of these diseases. These and similar discoveries show that it is chiefly by their chemical products that bacteria produce their effects, and hence it is to chemistry that much of the whole problem of infectious disease will have to be referred.

But there is another great question now under investigation of extreme importance-namely, What is the reason that so many infectious diseases leave the patient immune against another attack? Two different answers are givenone from the laboratory of the chemist and one from the laboratory of the experimental pathologist. The chemist says that bacteria as they grow in a medium finally generate poisons which wholly neutralize their action, and that these secondary poisons can be isolated from the blood of animals which have become immune against the original poison of the bacterium, and that this antitoxine, as it is termed, can be used to arrest a case of the disease by its counteracting the disease poison itself. In the treatment of that terrible affection, tetanus or lockjaw, this has been finally demonstrated within the past year to be the case, and it is proposed to extend this principle to the treatment of pneumonia and of many other infections. On the other hand, many experimental pathologists maintain that invading bacteria are met by hosts of the white corpuscles of the blood, which crowd to the seat of the infection and forthwith attack the invaders by literally eating them up. It is then only when the invaders are too strong in numcause, that the battle is lost for the body. Probably both of these views—that is, the antitoxine and the phagocyte, as it is called—are right; but it is evident that these vitally important questions are questions which only experimental medicine could either raise or settle.

(To be concluded.)

ciation in 1888,\* I gave the details of observations upon the tremors of paralysis agitans, Graves's disease, multiple

sclerosis, hysteria, neurasthenia, and alcoholism, the tracings of which were taken with the Edwards sphygmograph. The rate of these tremors, as determined in this way, I made out as follows:

,	o the second.
Paralysis agitans	3.7 to 5.6
Morbus Basedowii	8.7 to 12
Multiple sclerosis	5.4
Hysterical tremor	7.7
Neurasthenic tremor	7.4
Delirium tremens	5.6
Chronic alcoholism	8.5 to 11.2
Ankle clonus in primary lateral sclerosis	6

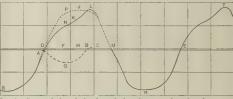

Fig. 3.—Geometrical analysis of paralysis agitans wavelet taken from upper right hand corner of Fig. 2.

While the sphygmograph does in reality serve sufficiently well for ordinary clinical purposes in the registration of these tremors, it is not satisfactory from a scientific point of view, because it is not exact in the determination of the rate. Take, for instance, the following table from my chapter on Paralysis Agitans in Starr's Familiar Forms of Nervous Disease:

Author.	Publication.	Rate to the second.
Charcot Ewald Grashey Huber	Contrib. à l'étude, etc. Md. du système nerv. Berl. klin. Woch., 1883, No. 32 Arch. für Psych., 1885 Virchow's Arch., vol. cviii, p. 45 Dis. of the Nerv. Syst., 1888, p. 1001	4-5 5 4:14-5:34 3:43-5:57

Curtis for placing it at my disposal.

In Fig. 2, on page 294, we have four tracings taken from a case of paralysis agitans, the drum being rapidly revolved so as to magnify the tremor waves. The movements represented are of the flexors and extensors of the

Fig. 7.-Tremor of paralysis agitans. Rapid revolution of drum.

wrist. The tendency to dicrotism is very pronounced, and the rate per second is seen to be exactly 5. Just beneath each tremor wave is the line indicating the seconds. Mr. A. E. Kennelly, of the Edison Laboratory, kindly volunteered to make a geometrical analysis of some of these waves, with a view to possibly determining some interesting features of diagnostic value. Thus, if the waves were constantly of the same character, we could always attribute a certain outline to a certain cause, and thus impulses and

value, for here the current velocity, the elasticity, and the resulting wave train are almost invariable. But where, as in the tremor waves above given, variation is considerable, such analysis is exceedingly difficult and must be carried

might be discovered. With a series of waves, such as is the second semi-wave, MRE, inverted, and the other a liquid waves through elastic tubes (the pulse), this careful smaller opposite wave in dotted line, A.G.B. The opposite geometrical analysis would undoubtedly prove of great wave has two thirds of the main wave length and one third

activities not visible in the aspect of the waves as a whole | half wave length be analyzed into components, one of which

of the main wave amplitude, so that (neglecting as a possible discrepancy the wavelet B C unaccounted for) there is a main train of waves, with a semi-train superimposed upon it, making a compound wave-train. Thus, as far as the tremor of paralysis agitans is concerned, this analysis merely serves to make the dicrotism more manifest. I trust that some one will apply the method to the more perfect waves of sphygmograms.

In the preceding tracings (Fig. 4), in another case, also taken from the wrist, the drum was revolved more slowly. The tremor rate of five per second is still very exact, and even the tendency to dicrotism is marked, though not magnified so greatly as in Fig. 2.

Fig. 5 represents in another case of Parkinson's disease the tremor of the thumb with a still more slowly revolving drum. The rate per second remains the same, but such a tracing is no improvement upon one obtained from a sphygmograph. The evenness of the tremor of paralysis agitans is the only characteristic feature.

Fig. 6 is a tracing also from the thumb, in another case where the tremor was very marked and the excursions wide. The revolutions of the drum were at the same slow rate as in the last. A remarkable feature of this tracing is a manifest tendency to a grouping of the waves about every four seconds, as if the innervation impulses were invigorated every few seconds. I could not determine whether this was due to some respiratory influence or to some unknown factor (such as nutritional rhythm in the cortical cells?). This is certainly worthy of further study. In another group of tracings, unfortunately lost, this peculiarity was much more pronounced.

Fig. 7 is a series of ring-finger tracings of the tremor of paralysis agitans with a rapidly revolving drum. While the rate of five per second is very apparent here, the greatness of the excursion prevents the development of the dicrotism, which was so marked in the cases where the wrist muscles were investigated.

In Fig. 8 we have the fine tremor of alcoholism greatly magnified by swift revolution of the drum. From a careful study of this tremor in a long series of many tracings I find the rate to be ten to the second. The above tracings show merely one or two seconds out of five or six on the same piece of paper. The uniformity of the tremor is also marked. Some tremors of Graves's disease and of general paresis were so similar in character and rate (ten to the second) that they are not reproduced.

Some time ago I called attention to a variety of post-hemiplegic movements (Trans. N. Y. Neurolog. Soc., Dec. 6, 1892) following infantile spastic hemiplegia, to which I gave the name methemiplegic polymyoclonus. It is a rare phenomena, for out of over two hundred and fifty cases of infantile cerebral palsies that have come under my observation I have seen but two with this form of morbid movement. It consists of rapid and not synchronous clonic spasms in the muscles of the limbs affected. The excursions of the separate muscles are about equal to those of paralysis agitans and the rate is five to the second. Indeed, if the muscles moved synchronously, the condition would be exactly analogous to paralysis agitans. The tremor is

constant, and only ceases during sleep. It would be improper to call it either athetoid or choreiform, and hence my selection of a new designation. The character of this movement is indicated by Fig. 9. Here the whole hand clasped a bulb connected with the tube leading to Marey's tambour and the delineator. The inco-ordinated and rapid movement is shown in the irregularity of the wave train. The drum revolved slowly in fifty-three seconds, and only about a third of the completed tracings is shown. The movement in the thumb alone is shown in the three tracings of Fig. 10.

In closing I will merely say that compared with the kymograph the sphygmograph is of course crude and uncertain in the registration of these various tremors. Most tremors can, I think, be placed in two categories—one a fine and rapid tremor at the rate of ten to the second, corresponding to the normal innervation rhythm as determined by Horsley and Schafer, and one a slow tremor wherein the normal innervation wavelets are fused into groups of two, giving an apparent rate of five to the second.

# THE PRESENT STATUS OF INTUBATION IN THE TREATMENT OF CROUP. By J. O'DWYER, M. D.

Most difficult would be the task of the impartial reader who would attempt to arrive at any definite conclusion regarding the value of intubation from the most careful study of the literature of this subject, unaided by personal experience. So conflicting are the opinions that have been expressed by the numerous writers on this subject, that the partisan, choosing whichever side his fancy or prejudice might dictate, could produce an array of authorities and statistics in support of his arguments, either pro or con, that to the inexperienced would appear overwhelming. Jumping at conclusions from a limited experience, the one thing above all others that the practice of medicine should teach us to avoid is the principal cause that has led to the confusion and difference of opinion that still exist on this question. The more fatal a disease, the more caution is necessary in making deductions from the evidence derived from a few cases, because, under these circumstances, the element of chance or coincidence often plays an important part which is excluded when large numbers are considered. For example, I recently intubated a patient for a physician in my neighborhood, who informed me that it was his eighth case of this kind, and that seven of them had recovered. For another physician, only a few blocks distant, I had intubated a similar number of cases, every one of which died. At the Great Ormond Street Hospital, London, in the year 1890, intubation was first tried in eleven cases of croup with only one recovery. This result was considered sufficiently unfavorable to condemn the operation, and it was therefore abandoned. At the end of two years, owing probably to more favorable reports from other quarters, it was again tried in another series of eleven cases, this time with eight recoveries (British Medical Journal, July 22, 1893). Whether only one patient or eight patients out of

cleven recover proves absolutely nothing except that some patients do recover after intubation. Neither would it have proved anything had every one of the twenty-two died, except that the mortality following intubation for croup was very large—a fact which no one with sufficient experience disputes. The literature of intubation abounds with similar examples of reaching conclusions from a limited experience, and it is on such evidence that this procedure has been overestimated by some and condemned as useless by others, according to the varying results obtained in a few cases.

The fatal and complex nature of croup, which renders such contradictory results possible under the same method of treatment, is also to some extent responsible for this condition of things.

Acute non-traumatic stenosis of the larynx in children that endangers life by suffocation is, with rare exceptions, diphtheria, either true or false. This disease, if unrelieved by mechanical means, proves fatal in about ninety per cent. of the cases, and, with all the aid that medicine and surgery can afford, it still continues to be, with few exceptions, the most fatal of all the acute diseases. The much-dreaded Asiatic cholera seldom carries off more than half its victims, while croup claims a much larger percentage. Even some epidemics of cerebro-spinal meningitis are more merciful than this disease, the terrors of which are less apparent because always present.

In considering the causes that lead to such frightful mortality and the unsatisfactory results obtained from any method of treatment yet devised, the important fact is often lost sight sight of that the word croup means a good deal more than obstruction in the larynx. Did it only mean the latter, there would be no room for any difference of opinion as to the best method of treating it, because under these circumstances intubation in skillful hands would have no failures.

Those familiar with the pathology of this disease know that the most frequent cause of death, after the laryngeal stenosis has been overcome by means of intubation or tracheotomy, is the extension of the disease to the bronchial tubes, where surgery can not reach it; and that there are several other causes, such as pneumonia, systemic poisoning, paralysis, especially of the heart, and nephritis, each of which contributes its quota toward swelling the mortality of this terrible disease. It goes without saying that the results of any method of treatment in a disease having so many complications, the fatality of which is so great under all circumstances, and which varies so widely in different epidemics, must be obtained from a large number of cases in order to be of any value. Not even are the results of intubation obtained from a large number of cases collected from numerous operators, each contributing a few, of much value, because the ability to intubate without immediate danger to life can not be acquired by the amount of practice derived from a few cases.

It is therefore to large individual experience alone that we must appeal for conclusive evidence as to the value of intubation, not only as a means of saving life, but also as to its more important function as a means of euthanasia in

the most excruciating of all forms of human suffering—that of slow strangulation.

There are at present a sufficient number of operators, both in this country and Europe, who possess this kind of experience, and they speak on this subject with no uncertain voice. Among the American intubationists who have had large individual experience and whose opinions on this question are well known I may mention Waxham, formerly of Chicago, now of Denver; Brown, Northrup, Huber, Caillé, Lester, Stanton, and the author, of New York; McNaughton, of Brooklyn; Hailes, of Albany; Eichberg, of Cincinnati; Richardson and Henrotin, of Chicago; Shimwell and Montgomery, of Philadelphia; Cheatham and Pusey, of Louisville; von Glahn, of Cleveland; Pyne, of Yonkers; and Graham, of Toronto. All of these and many others whose names I have not at hand have each had in the immediate neighborhood of or exceeding a hundred cases. Several of the operators mentioned can count their cases by hundreds, and four names could be selected whose aggregate number of cases now exceeds two thousand.

The latest intubation statistics are those by Dr. Mc-Naughton and Dr. Maddern, of Brooklyn, who have collected from 242 operators in various parts of this country and Canada 5,546 cases, with 1,691 recoveries, or 30.5 per cent. (Brooklyn Medical Journal, August, 1893). Notwithstanding that it is only within the last three or four years that intubation has been adopted to any considerable extent in Europe, some valuable statistics have already been accumulated. And these statistics are valuable not only because they are the result of large individual experiences, but also from the fact that they have been obtained exclusively from children's hospitals in which tracheotomy had hitherto been the only surgical measure available in the treatment of croup.

Professor Ranke, of Munich, as the result of a collective investigation on the subject of intubation in Germany, reports 1,324 cases of primary laryngeal diphtheria intubated, with 516 recoveries, and 121 cases secondary to measles, scarlet fever, pneumonia, etc., with 27 recoveries—a total of 1,445 cases, with 553 recoveries, or thirty-eight per cent. (Münchener medicinische Wochenschrift, No. 44, 1893). Of this number, Ganghofner, of Prague, contributed 498 cases, with 213 recoveries, 42·7 per cent.; Ranke, of Munich, 368 cases, with 128 recoveries, 34·7 per cent.; von Muvalt, of Zurich, 106 cases and 38 recoveries, 35·8 per cent.; Jaburowski, of Cracow, 165 cases and 73 recoveries, 44·2 per cent.; and Unterholzner, of Vienna, 164 cases and 55 recoveries, 35·5 per cent.

Secondary tracheotomy was resorted to in 250 of the cases, with only 20 recoveries, or about seven per cent.

In regard to the value of these statistics Ranke speaks as follows: "This number proves for itself that O'Dwyer's intubation, which at first and until lately was severely fought on all sides, has in the course of a few years gained more and more friends on this side of the Atlantic, and it proves that the dangers which were formerly charged against intubation must have been very greatly exaggerated."

And again, in giving the true explanation of the insig-

nificant results obtained by means of secondary tracheotomy after intubation had failed, as follows: "The extraordinarily small percentage of recoveries from these secondary tracheotomies is explained in this way: that in the majority of these cases secondary tracheotomy is resorted to after the diphtheritic process has extended to the bronchi, and that, under these circumstances, tracheotomy could not accomplish any more than intubation."

Similar testimony as to the value of this procedure comes from Hungary. Bokai, medical director of the Stefanie Children's Hospital of Budapest, has already intubated over 500 cases of croup, with recoveries of thirty-six per cent. In the medical report of the hospital for the year 1892, with an experience at that time of nearly 300 cases, Bokai, after referring to the necessity of having an additional diphtheria pavilion constructed, proceeds as follows: "That this construction was required was demonstrated by the fact that all the beds and extra rooms were continuously filled. The cause of this great attraction of our diphtheria division was due chiefly to the employment of intubation, and it gives us pleasure to be able to state that this procedure has given splendid results, so that tracheotomy has become almost wholly superfluous. In consequence of these splendid results, numerous friends have been added to the side of intubation, both in the country as well as in the city, and many colleagues have availed themselves of the rich material at our disposal to practice intubation under our direction. Convinced of the extraordinary importance of O'Dwyer's intubation in hospital as well as in private practice, I deemed it my duty to so instruct my colleagues, and it gives us pleasure to say that this acquisition has spread from our hospital throughout all Hungary."

Such is the evidence regarding the present status of intubation in Europe furnished by men whose reputations are more than national, and whose experience with this procedure has been amply sufficient to entitle them to speak on this subject with the voice of authority.

It will be noticed that the percentage of recoveries is considerably larger in Europe than is generally obtained in this country, and the same is also true of tracheotomy. The ready accessibility at all times of a skilled intubationist should give some better results in hospital than in private practice, which may in part explain the difference, as the statistics from the other side come exclusively from the hospitals, while in this country they are furnished, with few exceptions, from private practice. In 186 patients treated at the Willard Parker Hospital in New York, thirty-eight per cent. recovered, while at the Boston City Hospital 392 cases gave only twenty per cent.

In the former the resident physician and one trained assistant performed all the intubations, while in the latter they were done by successive house staffs, each member of which had charge of the diphtheria division in rotation. Under the latter circumstances the individual experience was necessarily small, so that no single operator could have had a sufficient amount of practice to enable him to avoid the accidents, not infrequently fatal, that are inseparable from intubation in the hands of the novice. That the dif-

ferent conditions which existed in these two hospitals explain the great discrepancy in the results I do not believe; but that they were sufficient to produce a very considerable difference in the percentage of recoveries there is not the slightest room for doubt.

In regard to the comparative merits of intubation and tracheotomy as life-saving measures in the treatment of croup, I do not know of any stronger argument that could be produced in favor of the new procedure than a short quotation from a paper by Dr. L. S. Pilcher, of Brooklyn, during a discussion on this subject before the Kings County Medical Society (Brooklyn Medical Journal, August, 1893).

Dr. Pilcher, while advocating the claims of tracheotomy as the greater life-saving operation, makes the following very candid statement: "I believe that it has been my lot to be called upon to do tracheotomy for the relief of croup in a considerable proportion of the cases that have sought surgical relief, and yet during the seventeen years during which I have been operating I have been called upon to do the operation but 66 times, notwithstanding the deaths from croup in our city during this period amounted to between 400 and 500 every year. On the other hand, during the past four years Dr. McNaughton has been called upon to intubate 142 times. He has been instrumental in saving 42 lives in four years, I but 22 in seventeen years, notwithstanding 33.33 per cent. of my cases recovered and but 29.5 of his." In other words, Dr. Pilcher was doing tracheotomy on an average of four times in a year, when the deaths from croup during the same period amounted to between 400 and 500.

Estimating from the deaths as given above, the total number of croup cases that occurred in Brooklyn during the seventeen years referred to was somewhere between 8,000 and 9,000, and out of this vast number the most celebrated tracheotomist of that city succeeded in saving the lives of only 22. This is a good example of the life-saving qualities of tracheotomy, an operation which the poorer classes, among whom croup principally prevails, seldom consent to, and if they did the skilled nursing so essential to the proper after-treatment would not be available. Intubation, on the contrary, is rarely objected to by either the rich or the poor, the ignorant or the intelligent, and no skilled nursing is required, the one and only requisite being trained operators. Outside of hospital practice there is, therefore, no room for comparison between these two procedures, the question as to whether, in a given number of cases, one operation may save a small percentage more or less than the other being one of scientific rather than of practical interest.

The difficulties and dangers of placing a tube in the larynx or removing it in the short space of time that is compatible with safety are either great or small according to the practical experience of the operator. When this important fact shall have been more generally recognized intubation will not be attempted by so many as heretofore, but will be left to those who have had some sort of preliminary training, if not on the cadaver, at least on a larynx, or on one of the smaller animals. By any of these means sufficient dexterity with the use of the instruments

may be acquired to avoid at least some of the accidents inseparable from this operation in the hands of beginners.

967 LEXINGTON AVENUE.

# ACUTE LACUNAR DIPHTHERIA OF THE TONSILS,

WITH STUDIES ON THE RELATION OF THE REAL TO THE PSEUDO  $BACILLUS\ DIPHTHERLE.$ 

#### BY HENRY KOPLIK, M. D.,

ATTENDING PHYSICIAN TO THE GOOD SAMARITAN DISPENSARY; ASSISTANT ATTENDING TO THE MOUNT SINAI HOSPITAL (CHILDREN'S WARD), NEW YORK.

The class of cases forming the subject of this paper are those in which diphtheria either begins or runs its entire course with the local picture of a lacunar or follicular amygdalitis. These cases, whose clinical study has been the subject of much difference of opinion, are becoming more important daily. It is through the avenue of these cases that diphtheria, sometimes of a fatal character, is unsuspectingly spread broadcast. If we are to advance in the prophylaxis of diphtheria we must do this not through means of the pronounced cases, in which the membrane is apparent even to the lay observer, but through the cases which in every way simulate the ordinary "sore throat," or tonsillitis, or lacunar or follicular amygdalitis. In my first paper upon diphtheria published in this journal I made a study of the doubtful cases of diphtheria. In those cases the diphtheria began or persisted as a simple angina or was manifest in the form of minute doubtful specks of exudate, "punctate membrane" upon the tonsils or soft palate, or was found to begin or run its course as an amygdalitis, or, beginning as a lacunar amygdalitis, would terminate in a descending diphtheria with stenotic symptoms. For the sake of unity the writer has confined himself in the present paper to the study only of those cases of diphtheria which begin or run their entire course with the clinical picture of a typical lacunar amygdalitis.

Anatomically the assumption of a form of diphtheria which may present a lacunar distribution can be more easily understood if we study what transpires in the normal tonsil as well as in the inflamed structure. Stöhr proved conclusively that in the tonsils there is normally a constant diapedesis of leucocytes from the central follicles of the organ through the several layers of flat epithelium on the surface of the tonsil. These leucocytes reach the surface of the tonsil and are found in small masses between the epithelial cells of the external layer of the tonsil. They are thrown thus into the cavity of the mouth and are found also in the lumen of the lacunæ.

Heubner, studying the abnormal conditions that are found in diphtheria, states that this normal lymph current, if we may so call it, is replaced by an abnormal exudate of lymph and fibrin from the vessels in the interior of the tonsil. This fluid is exuded through the several layers of surface epithelium, and when it reaches the surface of the tonsil it coagulates. Its youngest form is in the shape of a coagulated network of fibrinous exudate, containing in its meshes the flattened horny epithelium of the uppermost

layer on the tonsil. Thus for the first few days in the history of diphtheria we may have this coagulated exudate manifest itself in streaks or spots on the surface of the tonsil, indicating the situation of the lacunæ, follicles, or crypts, and the irregularities of surface between these structures. It is foreign to the purpose of this study to enter the pathological field dealing with the structure of the forms of diphtheritic exudate or membrane.

(N. Y. MED. JOUR.,

Modes of Investigation.—The cases studied in this paper have been investigated both from a clinical and bacteriological standpoint. As to the latter mode of study, the methods pursued in all cases were exactly those utilized in the first paper of the writer which appeared in this journal August 27, 1892. Special stress is laid upon the animal experiment as the only positive proof of the virulence of the Loeffler Bacillus diphtheriæ. From the ordinary crude clinical, diagnostic, or hygienic standpoint it can be said that an adept can easily identify the Loeffler bacillus by its form, lack of motion, growth on media, and bouillon reaction (Roux, Yersin, Escherich), without going through the tedious animal tests. Yet this method, moderately certain for rapid diagnosis, is scarcely available for permanent and reliable scientific work.

The cases in this paper have thus been subjected to the above mentioned test and the number is limited. After proving certain theses the further accumulation of material has no additional scientific value.

Clinical Course.—The cases collected in this study divide themselves quite distinctly into three leading groups.

The first group of cases are those whose course is an exceedingly mild one-so much so that the patients show little or no constitutional disturbance. The appetite is good; the children are up and about; they complain of slight uneasiness in the throat; sometimes these throat symptoms are absent. Examination of the fauces shows a general hyperæmia; the tonsils are enlarged. When the patient gags, the tonsils become still more prominent and reveal the enlarged open lacunæ. There is absolutely no membrane to be seen on the surface of the tonsil, but there is a yellow spot here and there which, on investigation, will be shown to be the opening of a lacuna or follicle or crypt. The lymph nodes at the angle of the jaw may or may not be enlarged. The above-described local symptoms are so mild that they may have improved or even disappeared the following day. The patient then is to all intents recovered from this so-called attack. We will show the fallaciousness of this assumption in our cases.

Case I.—Boy, aged six years, has been ill only for twentyfour hours; complains of soreness in his throat. Inspection
shows the lacunæ filled with a fibrinous material on the right
side, which can be scooped out of the tonsillar lacuna without
difficulty. There is on the surface at the anterior border of the
tonsil a minute fibrinous streak. Lymph nodes at the angle of
the jaw on the right side enlarged. Temperature 101.8° in the
axilla; the boy's condition is excellent and he does not feel ill.

Bacteriological examination of the fibrinous plug removed from the lacuna of the right tonsil and spread upon blood serum and subsequently isolated shows Loeffler bacilli virulent to guinea-pigs in dosage of 0.5 c. c. of bouillon culture within fortyeight hours. On the following day the tonsils still large, but the fibrinous streaks of exudate had disappeared.

A week subsequent to the above, the boy had completely recovered and the tonsils had returned almost to the normal size and appearances; they were still a little large and slightly red. A minute scoop was entered into the lacuna of the right tonsil as near as possible in the same situation as the first plug-This tonsil had this lacuna near the anterior border.

Diphtheria bacilli found virulent in same dosage as above.

Two weeks after the onset of the disease a similar plug removed from the same tonsil in the same locality.

Diphtheria bacilli still virulent in dose of 0.5 c. c. of bouillon culture forty-eight hours old.

At this time the appearance of the fauces was absolutely normal; no lacunar plugs to be seen. The above fibrin plug was extracted from the depths of the lacuna of the right tonsil. The case is continued in Part II of this paper.

Case II.—Sister of the preceding, aged eleven years, had absolutely no subjective symptoms, yet tonsils were enlarged and swollen, lacunæ open and wide, no elevation of temperature; child denies even soreness of the throat or any feeling of illness. Examination of the contents of the lacunæ scooped out as above shows what to all appearance were the Loeffler bacilli. They were not tested on animals.

A week subsequent to the first visit these bacilli had disappeared.

Case III.—Minnie B., aged eleven years. A baby sister of patient had been ill two months previous with what, from the history, might have been diphtheria. The mother, who from this time inspected the throats of the children daily, found on the day of the visit to the writer slight redness in the throat.

Status.—Tonsils are swollen and red; there is no membrane; the lacunæ contain a soft yellow substance which can be 10-moved in form of a plug (fibrinous). The whole picture one of lacunar amygdalitis. Temperature is slight, so that it was not taken. No glandular enlargements. Child in the best of spirits and condition. Examination of the plug, removed with sterilized scoop from the lacuna, showed diphtheria or Loeffler bacilli virulent in bouillon culture forty-eight hours old in dose of 0.5 c. c. to guinea-pigs.

Two weeks subsequently the angry appearance of the tonsils had disappeared. The one lacuna from which a yellow plug had been removed no longer showed reaccumulation of exudate. Child protests she is not ill and wants to return to school, which, of course, was not permitted.

Two weeks after the first examination a plug was removed from the lacuna in the same tonsil in about the same situation as the first plug. The bacilli in this plug were no longer virulent. They will be discussed under the heading of the pseudo bacillus.

In the above-cited cases we have a very mild form of tonsillar lacunar diphtheria—mild from the outset, watched all along its course, absolutely no membrane anywhere, and the children at no time during their illness in bed. The sterilized scoop, entered into the same tonsils at the same situation, showed that, as in the first case, there were bacilli in the depths of the lacunæ fully up to three weeks after the boy had shown no signs of lacunar plugs pouting from his tonsils. His case will be continued under the pseudo heading, and it will be shown that, as in Case III, the virulent was finally replaced by a non-virulent bacillus. Roux and Yersin, in investigations upon membranous diphtheria of the tonsils, recorded cases in which bacilli of Loeffler

had persisted for fully five weeks after the disappearance of membrane. The foregoing, I believe, are unique as showing the persistence of virulent bacilli in the depths of the tonsillar lacune for weeks after complete convalescence. The non-virulent bacilli found in Cases I and III will be discussed in the second part of this paper.

The second group of cases of lacunar diphtheria are those in which the symptoms, both local and constitutional, are somewhat more severe than in the first group of cases. The patients are quite ill; they suffer as do those patients who are affected with a severe follicular or lacunar amygdalitis of a simple infectious non-specific type (streptococcus). The fever is quite high, the prostration is more marked, and there are other symptoms of constitutional disturbance, such as pains in the limbs, furred tongue, and loss of appetite. Locally the tonsils are seen to be enlarged, red, and there exudes from the lacunæ a soft yellow fibrinous exudate. There is no membrane on the surface of the tonsil. There are glandular or lymph-node enlargements at the angle of the jaw. The following will illustrate:

Case IV.—Annie C., aged four years, has been ill one day. She complains of sore throat; tonsils are quite large and red; they present the typical appearance of a lacunar amygdalitis. When the patient gags, the tonsils protrude pink-red in color and from the lacunæ there is expressed by the act of gagging a soft, yellow, consistent material. Temperature 101°, axillary. Child shows some prostration, but general condition is good Lymph nodes at the angle of the jaw on the left side can just be felt.

 $\label{lem:examination} Examination \mbox{ of the lacunar contents as exuded shows Loef-fler bacilli in almost pure culture, virulent.}$ 

CASE V. -In this case the amygdalitis was complicated by symptoms of laryngeal involvement. These cases are important, showing as they do that, no matter how typical the lacunar amygdalitis, the larynx may be affected not by a simple but by a diphtheritic process, as are the tonsils themselves. These cases are especially apt to be judged as simple and non-specific.

Case VI.—Male, aged five years, has been coughing for three days. The tonsils are enlarged and have the typical follicular appearance. When the boy gagged it seemed as if the uvula, which curved upward, showed a minute yellow speck at its point. The voice is harsh and the cough croupy. No laryngeal breathing. Prostration marked. Bacteriological examination of the lacunar contents showed Loeffler bacilli.

The third group of cases of lacunar diphtheria are those which from the outset show a malignant course. They do not remain of the pure lacunar type after the first few days. In the following case the change occurred on the third day. The nasal mucous membrane is drawn into the symptomatic picture of the disease. We thus have a case beginning in every way like a severe follicular amygdalitis of a non-specific type (streptococcus), ending in a fatal diphtheria with pronounced septic diphtheritic phenomena.

Case VII.—Baby, female, aged thirteen months. There had been a number of cases of "sore" throat in the family (seven children), especially in that of a boy of eight years, whose throat, I regret to say, I did not examine bacteriologically. There was no membrane in this boy's throat, and there was every appearance when I saw him of a simple non-specific angina. The mother also had suffered from a "sore" throat. The symptoms in all cases had been so mild as not to call for

any outside advice. The baby had been ill for two days when first seen. The infant was very pale and quite prostrated; rectal temperature, 102°. The lymph nodes on both sides of the neck, at the angle of the jaw, were much enlarged in packets. There was no skin eruption. The tonsils were enlarged, red, eroded, but had the appearance of a very severe lacunar amygdalitis; no nasal discharge. The following day the tonsils appeared less swollen and the amygdalitis an ordinary one. In view of the constitutional symptoms and a slight nasal discharge, I warned the mother to allow me to see the patient again if improvement was not rapid. Two days subsequent to this the tonsils had again swollen; the discharge from the nose became much more pronounced. The tonsils were so much swollen as not to permit a view of the posterior pharynx. The discharge from between the tonsils now contained minute shreds of what proved to be membrane.

Bacteriological examination of these shreds show Loeffler bacilli and large numbers of Roux's cocci. The case ended fatally, with symptoms of septic diphtheria, including extensive glandular infection.

The Diagnosis.—The constitutional symptoms give us very little clew to our diagnosis in the first group of cases, whereas in the third group the severe constitutional prostration from the outset leads us to suspect something more specific than simple amygdalitis.

The range of febrile disturbance is also quite unreliable. Glandular swelling may be practically absent in the mild cases, though it will be seen that in some of these cases we had as an accompaniment of the diphtheria a swelling of the lymph nodes on one side only. On the other hand, glandular swelling may be very marked in non-diphtheritic amygdalitis (streptococcus). The swelling of nodes on one side is peculiar to diphtheria, though I have very often seen it in non-diphtheritic cases. Albuminuria may be present or absent at first, when diagnosis is most important. It is apt to be present in simple streptococcus disease as well as in the diphtheritic cases.

Henoch says, in a recent article upon the early clinical diagnosis of diphtheritic amygdalitis, that we must judge our cases from the consideration of a completed picture of the disease. It will also be seen that the diagnostic elements presented by this great clinician—the fibrinous exudate from the lacunæ, the confluence of patches of fibrin on the surface of the tonsil, affection of both tonsils, the uvula and nasal mucous membrane, albuminuria, the occurrence of several cases in one family-all apply either to the severe cases (third group), or appear late in the disease. To the writer it still seems that the only reliable test is the bacteriological one. There is now such a reaction as to encourage the hope that soon this test will be applied by the general practitioner in daily practice.

#### PART II .- BACTERIOLOGICAL.

The methods pursued in the investigation of the cases in this paper included not only an examination of the secretions on the surface of the affected tonsils, but what seemed more interesting and, in fact, imperative was the examination of the contents of the individual lacunæ of the tonsils. The lacunæ could only be studied in the older children,

introduce a minute sterilized scoop or harpoon. In this way the plug or secretion in the depths of the lacunæ was obtained for study, spread upon serum, and isolated finally upon agar-agar. The writer has been impressed by the fact that the tonsil may harbor for weeks in the depths of its lacunæ, follicles, or crypts, as we may choose to call these structures, virulent diphtheria bacilli. In membranous diphtheria we are not surprised to find, after the membrane has cleared away, that the diphtheria bacilli persist in the numerous ulcerations or erosions left by the membrane on the surface. In lacunar diphtheria, as in Cases I and III, where no membrane is formed in the whole course of the affection, we are surprised to find in the depths of the lacunæ fibrinous plugs which persist for weeks and which contain myriads of virulent bacilli. Roux and Yersin found that in cases of membranous diphtheria the Bacillus diphtheria persisted in a virulent state as long as five weeks after all traces of membrane had disappeared from the fauces. I have had this condition of things repeated in lacunar diphtheria. The virulence of the Bacillus diphtheriæ can be preserved for an exceedingly long time outside of the body. It resists the drying process if shielded from the direct sunlight. A culture of the Bacillus diphtheria in the author's possession, after having dried for months in an ordinary test-tube, so that the original agar was reduced to a dry crisp, showed after nine months a virulence in bouillon forty-eight hours old to the amount of half a cubic centimetre to old or young guinea-pigs. The scrapings of such a culture, though containing many involution forms such as have been pictured by the writer in his first article, grew most luxuriantly in agar and bouillon. Old bouillon cultures, reduced by age from evaporation to a few drops from ten cubic centimetres, were found to abound in virulent living bacilli which grew upon agar. Roux and Yersin, in their last article upon diphtheria, assume that the mild cases may yield bacilli which show a diminished virulence in animal experiment. The writer's experience, at least in the class of cases examined, does not tend to confirm this view. Bacilli from the very mildest cases of lacunar diphtheria were found in pure culture virulent to guinea-pigs in dosage of half a cubic centimetre of bouillon culture forty-eight hours old. This dose is now conceded by most writers to be small enough as a test of virulence. All animals injected with such an amount died within forty-eight hours with symptoms of virulent diphtheria (local hæmorrhagic ædema, enlarged lymph nodes, pleuritic and peritoneal effusion).

In Case I the Loeffler bacillus was isolated three weeks after all traces of tonsillar trouble had disappeared. These bacilli were preserved in separate cultures pure, and those isolated latest were found fully as virulent as the bacilli isolated at the outset of the disease. All these bacilli were cultivated from the lacunar plugs so often mentioned in this paper. A dose of half a cubic centimetre of a bouillon culture invariably proved lethal to guineapigs of medium weight (three hundred and fifty to four hundred and fifty grammes) within forty-eight hours. In this way the bacilli obtained from the mild cases. were compared with a very old culture which has been where they are of some size and in which it is possible to in the author's possession over two years and which has been isolated by him from a virulent membranous diphtheria. Of this culture a tenth of a cubic centimetre will prove lethal to animals in varying time, but half a cubic centimetre will invariably prove lethal in forty-eight hours if bouillon cultures forty-eight hours old are used. In short, bacilli of a so-called diminished virulence—those which would require two or three cubic centimetres to prove lethal from bouillon cultures forty-eight hours oldwere sought by the writer in the mild cases, not of membranous but lacunar diphtheria, and were not found. In the author's experience, the mildest cases furnish as virulent bacilli as the most severe. In all this we assume that certain fixed laws in the preparation of all cultures are followed. The agar cultures are made from single colonies upon alkaline agar one per cent. These agar cultures are taken out of the thermostat after forty-eight hours. Bouillon cultures of simple pepton alkaline bouillon are prepared from these agar tubes. The bouillon is taken out of the thermostat after forty-eight hours. The animals used in testing virulence are always young animals, three hundred and fifty to four hundred and fifty grammes in weight. The bouillon cultures should be eight to ten cubic centimetres in bulk and the supernatant fluid above the sediment should not be poured off, as has been done by many authors, and the thick residue used, but the whole culture is shaken up and half a cubic centimetre of this is used. Old animals even of medium weight show a certain amount of resistance to diphtheria and should not be used. The above are brought to the notice of the worker in diphtheria as a result of a long and tedious series of studies in this field. They will insure uniform results. .

The Pseudo Bacillus Diphtheriæ (Hofmann, Loeffler).—
In the first paper of the writer four cases were recorded in which a bacillus was found which closely resembled the real bacillus, reacted much the same upon culture media, but lacked virulence completely. In the studies of this paper the writer has succeeded in isolating a bacillus from cases in which the virulent diphtheria bacilli had been found and which appeared in the same patient after a lapse of weeks. In ordinary stained preparations (Loeffler blue) an expert would have great difficulty in finding marked differences of form. They were lacking completely in virulence.

The relationship of the real to the pseudo Bacillus diphtheriæ has lately been the subject of a critical review by Escherich. This critique was incited by the surprising discoveries of Fraenkel, who described a bacillus which in every way corresponded to the true Loeffler bacillus as to culture and stain, but which differed from it only in lacking virulence. Doses of two cubic centimetres seemed to be well borne by animals, whereas in five-cubic-centimetre doses of a bouillon culture a lethal result followed. Fraenkel isolated his bacillus from the human conjunctiva in cases in no way related to diphtheria. He concluded from his observations that he had before him the true Bacillus diphtheriæ, but reduced in virulence; that the bacillus he had isolated and the Hofmann pseudo bacillus were identical. In this way he championed the cause of Roux and Yersin, who maintain the same ground. Escherich does not agree with these observers. The writer of the present of course, vary widely from above.

paper is inclined to look upon the whole question of relationship of these two bacilli as an open question. But little has been proved on either side. The question is one of the widest range of importance. If the real Bacillus diphtheriæ can so completely lose its virulence as will be seen in the bacillus isolated in this study, certainly all known means have as yet failed to bring it back to its original state of virulence. Pasteur, in reducing the bacillus of charbon to a non-virulent organism, did so by artificial means outside the animal economy. I therefore do not consider this fact brought forward by Roux and Yersin in support of their views as quite apt or all-satisfying.

The following studies are certainly unique and are published at this time as peculiarly pertinent to this very important question of the relationship of the real to the pseudo Bacillus diphtheriæ.

Cases in which a bacillus, non-virulent, replaced the real Bacillus diphtheriæ after a lapse of time:

Case I, lacunar diphtheria, virulent Bacilli diphtheriae found up to three weeks after convalescence, then the non-virulent bacilli were found.

If the reader will refer to Case I of the first group of cases of lacunar diphtheria it will be seen that up to the third week after the onset of the illness, and fully that time after the boy felt well and the tonsils had cleared, the tonsils and pharynx were in appearance normal, and were the seat of virulent bacilli.

Three weeks, therefore, after the onset of the illness a sterilized silver scoop was introduced into the lacuna of the right tonsil and a fibrinous yellow plug was removed. This plug was found to contain almost exclusively a bacillus in every possible way as to shape and stain the exact counterpart of the real Bacillus diphtheriæ. It was non-motile, stained with Loeffler blue in broken areas, and was not decolorized by Gram. There were clubbed shapes and involution forms in abundance. A very close study of the virulent bacillus taken from the same case and tonsil earlier in the disease (fourteen days after the onset) and this present bacillus side by side showed a very slight difference in thickness of the two bacilli; the non-virulent seemed to stain a little thicker, but so slight was this difference that unmarked there is for practical diagnostic purposes but very little to fix upon, for at times the virulent bacilli are thicker than others, short and long. The length of both bacilli seemed and still appears identical. In growth there are distinct differences.\*

Bouillon is uniformly clouded after forty-eight hours and the deposit is much more abundant than that of the virulent bacillus. The reaction of the bouillon is distinctly alkaline after forty-eight hours.

Agar-agar yields a growth in which we at once notice a luxuriance foreign to the virulent bacillus. The colonies upon agar-agar reach a fuller development in shorter time than the real bacillus. They seem whiter and more opaque.

The above non-virulent bacilli were found up to the end

<sup>\*</sup> Measurements of the Loeffler virulent bacillus: Length, 2°2  $\mu$  to 5  $\mu$ ; width, 0°6  $\mu$  to 0°8  $\mu$ . Some non-virulent bacilli (pseudo) of same case: Length, 2°6  $\mu$  to 4  $\mu$ ; width, 0°6  $\mu$  to 0°78  $\mu$ . Involution forms, of course, vary widely from above.

of the fifth week after the onset of the illness and were isolated in pure culture and are in the possession of the writer. The attempt to find them in the tonsil six weeks after the onset of the illness resulted only in their identification in smear preparations upon serum; they were overgrown in twenty-four hours by staphylococci.

Case II, in which the virulent Bacillus diphtheriæ is replaced in the same tonsil by a non-virulent bacillus.

This is Case III of the mild series of lacunar diphtheria cited in the first part of this paper (refer to history). The patient was seen four times, the second visit a day after the first. The tonsils had cleared, and the yellow streaks and lacunar appearances had disappeared; the tonsils were still red and enlarged. The Bacillus diphtheriæ, isolated from the right tonsil, had been found virulent.

Third visit a week after the first one, and the tonsils apparently normal in size and appearance: no culture made. Fourth visit, fifteen days after the first: tonsils normal; child well; a sterilized scoop entered into the lacuna of the right tonsil, behind the anterior faucial pillar, as near as possible to the place where the virulent bacilli had been extracted. A large, yellow plug, which had been invisible, was removed from the depths of this lacuna. From this plug there was obtained a luxuriant growth upon blood serum of a bacillus the exact counterpart of the non-virulent bacillus isolated from Case I above.

In the above two cases we have typical lacunar diphtheria in which no membrane was seen at any period of the disease, both of which cases were exceedingly mild in all their manifestations. In both cases the real bacillusvirulent-persisted for three weeks in one case and up to the second week in the other. The bacilli were all isolated from plugs of fibrinous exudate removed from the lacunæ and sown upon blood serum. The various sets of bacilli were kept separated, and tested and found all to be of a like virulence, as stated in another part of this paper. At the beginning of the fourth week in one case after the first isolation of virulent bacilli, and the beginning of the third week in the other case, these virulent bacilli of diphtheria were replaced by a bacillus which was in every way, except in growth upon agar and in bouillon, the most accurate counterpart of the virulent original bacillus. It was, however, in both cases a harmless, non-virulent bacillus. Loeffler, in his second article upon diphtheria, asserts that in a case of an adult he had found the virulent and the non-virulent bacilli growing side by side upon the agar plate, and had isolated both. In this way he accounted for the famous pseudo Bacillus diphtheria of Hofmann, saying that the pseudo bacillus was an accompanying harmless bacillus of the real micro-organism. Roux and Yersin found the non-virulent or pseudo bacilli in cases of membranous diphtheria which early in the disease had yielded the virulent bacillus. The writer's cases are the only ones in which the real and virulent bacillus was replaced in the same tonsil and, as near as could be judged, in the same locality, entirely by a rich growth of a non-virulent bacillus which the expert examination alone could only find the least remove thicker than the virulent bacillus, but of the same form and staining peculiarities. In order to be ex-

plicit, we wish to repeat that this bacillus is non-motile, grows more luxuriantly upon agar than the virulent bacillus and the bouillon cultures (peptone bouillon) are not acid, as in the real bacillus, but alkaline after forty-eight hours in the thermostat. The bouillon deposits a more abundant sediment than the virulent and is more diffusely clouded. Roux, Yersin, and Escherich have called attention to the early acidity of the bouillon cultures of the virulent bacillus (forty-eight hours), and the author has had ample opportunity to verify this important and invariable quality of the virulent bacillus. The non-virulent bacillus stains exactly like the virulent micro-organism both in Loeffler blue and Gram stains. As stated, it seems, when closely studied side by side with the virulent bacillus, broader than the latter. I doubt whether, in unmarked specimens, the writer's non-virulent bacilli could be distinguished by stain alone. We have the same clubbed and involuted forms shown by the virulent bacillus. I have noticed that it does not grow so luxuriantly in sugar bouillon as it does in the simple peptone bouillon. In the latter the shape of the non-virulent bacillus is more complete as a bacillus form after fortyeight hours than that of the virulent bacillus, which is often seen in abortive forms at this time in bouillon culture.

Animals do not react even to large doses (eight cubic centimetres of forty-eight hours' bouillon) of the non-virulent bacillus; a few guinea-pigs develop a slight ædema, which eventually disappears. After having received these large quantities of the non-virulent bacillus, four guinea-pigs were reinjected after the lapse of a week with half a cubic centimetre of the virulent bacillus with lethal effect in two cases within forty-eight hours; a third, in three days; and a fourth, an old, fully-developed pig, in four days. Thus the non-virulent bacillus was not a vaccine against the virulent bacillus. These experiments, it will be recalled, were also performed with the non-virulent bacilli isolated in four cases of the first paper on this subject by the writer with similar results.
